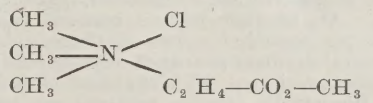
Hunt and Taveau in 1906 were the first to test acetylcholine physiologically and to demonstrate its main property—the lowering of arterial pressure. That this action is due essentially to dilatation of the arteries and arterioles has been proved by several workers besides ourselves (Dale and Richards, Krogh, Maurice Villaret, L. Justin-Besançon, and Mme. Schiff-Wertheimer). This action is elective, a subcutaneous injection producing no flushing of the face (no capillary dilatation), while the retinal artery on ophthalmoscopic examination is found to be twice its original volume. Until we introduced acetylcholine into therapeutics two years ago, no one seems to have ventured to administer this product to human beings, as its intravenous administration to animals proved very toxic. A dose of 3/10ths of a milligramme in 2 c.cm. of normal saline injected into a rabbit causes death from sudden collapse of arterial pressure, while its motor exciting action on the isolated uterus of the guinea-pig is 20 times stronger than that of pituitrin or pilocarpine. Compared with choline this acetyl derivative is 100,000 times more active on arterial pressure, but only three times as toxic.

Our primary research was the study of the pharmacological conditions necessary to produce a preparation of acetylcholine suitable for injection into human beings, and our subsequent work during the last two years has been carried out with the anhydrous hydrochloride salt, stabilised with glucose. Acetylcholine hydrochloride has the formula—



This body is very hygroscopic, and for human use certain precautions are necessary. It must be fresh and solutions must be prepared immediately before injection; for this reason we always use the stabilised anhydrous powder preserved in sealed glass ampoules. The purity of the product must be verified by chemical tests and its activity physiologically controlled, for only by having a product of constant composition can errors in dosage be avoided. Our clinical experiments and those of others have shown that acetylcholine can be administered without danger, provided that the injections are given subcutaneously or intramuscularly. Intravenously it is dangerous, orally it seems to have no action. The fact, however, that more than 2000 injections have been given by us personally and nearly 10,000 have been given in the Paris hospitals without one untoward incident affords ample proof that the therapeutic use of acetylcholine is in no way

dangerous, causes neither local nor general reaction, and produces no intolerance, and that its effect is wholly maintained even after repeated administration.

Apart from its main action on arterial pressure, as confirmed by the sphygmomanometer, we should mention its action on the heart, muscles, blood, and humoral equilibrium. On the heart its effect is similar to that obtained by faradic excitation of the pneumogastric, which explains why some physiologists consider this body to be the vagal hormone. This vagal action of acetylcholine has been verified by Henri Fredericq. It excites smooth muscle; in very extreme dilutions it stimulates peristalsis of the isolated intestine. This action is due to excitation of the parasympathetic, of which it is considered as the elective excitant. On striped muscle acetylcholine produces a contraction which is suppressed by atropine but not by curare. It has an anticoagulant action on the blood in vitro. Gautrelet claims that it has an antianaphylactic power. The importance of the effects of acetylcholine, its rôle, opposed on most points to that of adrenalin, and particularly its action on the heart, explain why Gautrelet and other physiologists consider it as a hormone.

Therapeutic Indications and Dosage.

Acetylcholine is given by subcutaneous or intramuscular injections; even large doses (0·2 g.) thus administered are painless and produce neither local nor general reactions. The therapeutic indications are numerous from the fact that its vaso-dilating property is localised on the arteries and arterioles, and further, on account of its effect on the vago-sympathetic equilibrium. Future research will, without doubt, extend its field of usefulness; the principal diseases in which we and others have verified its importance are Raynaud's syndrome, gangrene arising from arteritis, and other troubles of a like nature. Acetylcholine has no influence on the ordinary acro-cyanoses often occurring in young women who, in addition, show a submalleolar erythrocyanosis, a syndrome which one of us has described and proved to accompany a venous hypertension, consequently non-accessible to arterial medication. On the contrary, true Raynaud's syndrome is usually improved by acetylcholine. It is characterised by: (*a*) syncope of the extremities often changing quickly to local asphyxia, the fingers and toes turning purple or even black; (*b*) the presence of pain; (*c*) the occurrence of severe trophic change in the fingers and toes.

Acetylcholine acts by dilating the arterioles of the extremities; it is therefore obvious that when the disease has produced anatomic obliteration of these small vessels, no effect can be expected. The dosage is 0·05 g. subcutaneously the first day and 0·1 g. the following day. If in ten days the results are inadequate, doses of 0·2 g. may be given even twice daily, but in general the single daily dose of 0·1 g. is sufficient. An average course consists of 15 days' treatment per month for two or three months until there is complete disappearance of pain and of trophic and vasomotor signs. If a patient showing active signs of Raynaud's disease receives an injection of acetylcholine, in 10 to 15 minutes the fingers recover their normal colour. This coloration persists for from 12 hours to three days. Pains disappear rapidly, sometimes even after the first injection. The amelioration of trophic changes depends greatly on the extent of the secondary infection, which can very seriously affect the action of acetylcholine.

Arteritis with a Tendency to Stenosis.—When this is pre-senile, senile, or diabetic gangrenous, the effect of acetylcholine is often remarkable. Here the drug acts by dilating the anastomotic arterioles and by diminishing the spasm of the affected vessels, as is proved sometimes by improvement in the oscillometric index. As in Raynaud's syndrome, so in arteritis, there are a large number of failures whenever there is complete stenosis; acetylcholine naturally will not open out an obliterated artery. The dosage we have used is 0·1 g. morning and evening, increased after the first day to 0·2 g. morning and evening. The duration of treatment varies according to the extent of the anatomic lesions. If the case is mild 15 injections per month are sufficient; if the case is more severe the injections must be continued until there is improvement.

The proportion of failures is larger than in Raynaud's disease, for very often the arteries are completely obliterated; but even with arterial obliteration we have obtained the following results: (*a*) Disappearance of the intermittent claudication, generally after five or six injections. (*b*) Ease from pain; in some cases the effect is much superior to that of morphine. (*c*) Disappearance of trophic changes, provided, of course, that they are superficial and that the secondary infection is not advanced. Here also the secondary infection is capable of hindering the wonderful analgesic action of the medicament. (*d*) Increase of the oscillometric index. This is very uncertain, is only seen in the most favourable cases, and predicts improvement. (*e*) Pre- and post-operative treatment. Before every operation it is useful to give the patient a series of injections of acetylcholine as this often limits the extent of the operation, so that, for example, section below the knee may suffice instead of amputation at the thigh. We have seen many examples of this in Paris hospitals and other cases have been reported from abroad. (*f*) In diabetic arteritis acetylcholine plus insulin treatment is superior to insulin treatment alone, and in one case under our observation in which insulin treatment gave no results the pains disappeared immediately after a few injections of acetylcholine and the trophic ulcerations healed quite rapidly. (*g*) In a patient suffering from pre-senile arteritis, after failure of sympathectomy, acetylcholine caused disappearance of the pain from the first injection and very rapid cicatrisation of the trophic lesions.

Troubles and Complications of Arterial Hypertension.—It is well known that some patients with an arterial pressure of 300 mm. of mercury may have no functional troubles, while others with a pressure of 200 mm. have marked symptoms—giddiness, buzzing in the ears, cramps in the calves, dead fingers, defective vision, &c. These troubles seem to largely depend on arterial or arteriolar spasms and their treatment by acetylcholine is worth trial. On the arterial pressure figures themselves prolonged acetylcholine treatment can produce a reduction, especially of the maximum pressure. This, however, is very uncertain and in any case one cannot compare the effect of subcutaneous injections in man with the reduction obtained in animals by intravenous injections. Nevertheless we have a certain number of observations in which the arterial pressure has been favourably influenced. On the other hand, the effect of acetylcholine on functional troubles is very considerable. Cramps of the lower limbs, "dead fingers," sight disturbances, &c., disappear very quickly in most cases. In old people with atheromatous arteries there is danger in injecting too large a dose of acetylcholine; the risk of hæmorrhage in the nerve centres cannot be disregarded.

Indications in Ophthalmology.

Since publishing, in conjunction with Mme. Schiff-Wertheimer, the dilating effect of acetylcholine on the retinal artery several observations confirming our research have been reported on its use in spasms of this artery. The dosage given was from 0·15 to 0·2 g. by intramuscular injection. Bailliart cites a case of spasm of the retinal artery with Raynaud's disease, both troubles being cured by acetylcholine injections. Kalt published a very interesting case of thrombosis of the retinal artery with blindness, which was immediately arrested by acetylcholine; after the first injection the macular vision reappeared with a visual acuteness of 8/100. Important research has just been carried out by P. N. Deschamps and Gallois, and by Courland and Kahane, which shows that the injection of acetylcholine, particularly subconjunctival injection, produces a diminution of the tonus of the ocular globe. The last-named workers further claim

that the subconjunctival injection causes a considerable myosis lasting for a long period.

Tuberculous Sweats and Other Syndromes.

Finally, in the course of clinical research carried out in different directions, we have observed that acetylcholine constitutes an absolutely remarkable treatment for profuse tuberculous sweats. In these, small doses only are required; one to two centigrammes subcutaneously or intramuscularly every day or every other day. Stronger doses may produce absolutely opposite effects. In our experience this treatment is by far the best therapeutic measure.

The effect of acetylcholine on the arteries and arterioles has stimulated experiment in other syndromes, in particular angina pectoris, on which work is now taking place. Again, in different cases we have noticed that the injection of large doses produces an increase of intestinal peristalsis, resulting in the disappearance of habitual constipation. In lead colic, although only a few cases have come under observation, strong doses of acetylcholine (two or three injections of 0·2 g. every ten minutes) seem to give splendid results. Chavany has just published important data regarding the use of acetylcholine in cerebral spasms (transitory hemiplegia). It is possible also, judging from the first results obtained, that the therapeutic and diagnostic action of acetylcholine on the biliary and gastric secretions may not be without interest.

THE DIAGNOSIS AND TREATMENT OF SUBACUTE CHOLECYSTITIS.*

By WILLIAM BAIN, M.D. Durh., F.R.C.P. Lond., F.R.C.S. Edin.

In discussing the diagnosis and treatment of cholecystitis I shall confine my remarks to the early cases of subacute cholecystitis. The acute variety generally belongs to the domain of the surgeon; it is conceivable that an acute case may subside without surgical interference, but I have not seen such a case. Again, the majority of the chronic, or what I may call the neglected, cases of subacute cholecystitis will probably require surgical aid. These are the borderland cases, which may, or may not, yield to medical treatment.

Anatomy and Physiology.

When I first began to take an interest in this affection I could not obtain a description of the mucous membrane of the human gall-bladder, for the simple reason that it disappeared about 12 hours after death, but, thanks to the surgeons who have removed gall-bladders with practically normal mucous membrane, we are now acquainted with its histology. Bile is partly an excretion, carrying off certain waste products, and partly a digestive secretion, playing an important rôle in the absorption of fats. The bile-acids or their decomposition-products are partly absorbed from the intestines, and are again secreted by the liver. The significance of this reabsorption lies in the fact that the bile salts have a distinctly stimulating effect upon the bile-secreting cells of the liver. They also serve as a menstruum for dissolving cholesterin, which is always present in bile. It is suggested that cholesterin is obtained from the stroma of the red cells destroyed by the liver. The secretion of bile is continuous. The bile pressure averages about 30 mm. of mercury, which is about three times the pressure in the portal vein, thus showing that secreting cells exercise pressure. The capacity of the gall-bladder is small, and the amount of bile secreted in half an hour is quite sufficient to fill it. It has been proved that the amylolytic power of the pancreatic extract is doubled and the fat-splitting action trebled by the addition to it of bile or bile salts. During its stay in the gall-bladder the bile is concentrated by the loss of water and by the addition to it of mucin or nucleo-albumin. Stimulation of the spinal cord or splanchnic nerves diminishes the secretion of bile by constricting the abdominal vessels, but section of the splanchnic nerves may cause an increased flow. When bile is taken by the mouth or injected into the circulation it causes an undoubted increase in the secretion. It is probable that the bile salts have a specific action upon the liver cells. Weinberg states that peptones and proteoses have a marked stimulating effect upon the secreting cells of the liver and so has secretin. It is surmised that each gush of chyme into the duodenum causes, by reflex action, a contraction of the gall-bladder and a relaxation of Oddi's sphincter. The substances responsible for this stimulation are the fats. The contraction of the gall-bladder is not sharp and uniform, but slow and gradually increasing in intensity.

For the size of the organ the blood-supply is generous, and the gall-bladder has a large number of nerve-fibres derived from the vagus and sympathetic. The fibres emerge from the spinal cord in the roots of the sixth thoracic down to the first lumbar, and pass to the cœliac plexus. Slight stimulation of the vagus produces contraction of the organ with relaxation of Oddi's sphincter. Strong stimulation of the vagus causes a more pronounced contraction and a spasm of the sphincter. Stimulation of the sympathetic produces a relaxation of the gall-bladder and a contraction of the sphincter.

Dr. Wilkie's [1] recent experimental results are intensely interesting and illuminating. In his first experiments the entire gall-bladder was cultured, and in most cases no organism was discovered. He then isolated the streptococci from the submucous and outer coats in 42 per cent. of the cases. He suspected and showed that if any bile adhered to the mucous membrane this organism was not recovered. Then a brilliant idea was suggested to him by his brother, Prof. Wilkie—viz., that the cystic lymph gland should be employed for culture. This gland is nearly always enlarged in cholecystitis. In the cases investigated the lymph gland yielded a pure growth of streptococci in 86 per cent. *Bacillus coli* was frequently present in the bile but scarcely ever in the lymph drainage, which is antagonistic to the theory that organisms enter the wall through the lumen of the gall-bladder. When the streptococci were injected into the gall-bladder no change resulted and the bile soon became sterile. When the streptococci were introduced intramurally into the gall-bladder a typical cholecystitis developed within a couple of months. When the streptococci were injected intravenously, the first inoculation merely acted as a sensitiser, but the second and subsequent injections produced cholecystitis. In these experiments the gall-bladder changes corresponded exactly with those in the human gall-bladder. In long-standing experimental cases calculi were formed consisting of cholesterin if the cystic duct remained patent, but if the duct were partially or completely occluded the calculi were composed of cholesterin and bilirubin-calcium. Further, the experiments proved that the organisms reached the gall-bladder by the cystic artery, as all the lymphatics to and from the gall-bladder were severed. Wilkie has confirmed Rosenow's theory that organisms grown from certain lesions can reproduce experimentally

* A paper read at the Harrogate Medical Society in opening discussion on the diagnosis and treatment of cholecystitis.

[1] Wilkie, A. L.: Edin. Med. Jour., April, 1928.

similar lesions in animals. Rosenow was the first to suggest that the streptococci were, as a rule, responsible for the infection of the gall-bladder, but the evidence he produced did not carry conviction, whereas Dr. Wilkie's experiments must appeal to the most sceptical.

When the gall-bladder is inflamed other structures are also involved—for example, the functions of the liver cells and their excretory ducts are depressed and there is generally an alteration in the composition of the bile. In the early cases such evidence is obviously difficult to obtain, unless from a patient killed in a motor accident. However, I am tolerably certain that associated with cholecystitis there is more or less derangement of the liver functions. Wilkie [2] has recently published another series of experiments upon the gall-bladder. After producing cholecystitis experimentally, he killed the rabbits four months later. It was then found that the inflammatory process had extended to, and involved, the liver—"the cells were pale and hazy; inflammatory celled infiltration was present, and there was an increase of fibrous tissue in the interlobular areas." Presumably similar histological changes occur in human subacute cholecystitis.

Symptoms and Diagnosis.

The initial symptoms of cholecystitis are generally referable to the digestive system and are ascribed by the patient to stomachic disturbance; occasionally there are no symptoms, the condition being discovered during a routine examination. Unaccountable intermittent depression is not uncommon and may be the only symptom. Whenever a patient complains of indigestion which has not been relieved by dieting and the usual palliatives, a careful abdominal examination should be made. If the patient were thoroughly examined at the first consultation, mistakes in diagnosis would be reduced to a minimum and operations on the gall-bladder would become uncommon. The most important sign is tenderness on deep pressure over the gall-bladder when the abdominal wall is relaxed. In some cases the right rectus in the hypochondrium contracts on palpation, and occasionally it continues to contract for a week or so after the tenderness disappears. Very exceptionally I found this contraction present without any palpable tenderness. I should be glad if anyone can explain the cause of this physical sign. I regard the tenderness on pressure as pathognomonic, but there are certain pitfalls in eliciting it. Panniculitis over the gall-bladder area requires to be excluded; with ordinary care this is not difficult. In cholecystitis, if the superficial tissues are picked up between the forefinger and thumb over the gall-bladder area, there is scarcely any discomfort, whereas in panniculitis the process is intensely disagreeable. Massage will get rid of the panniculitis, but the manipulations should be confined to the superficial structures, as vigorous massage might aggravate an inflamed gall-bladder. The history of the case is also important in elucidating the diagnosis. Another pitfall is a movable kidney. On examining a neurotic patient without digestive disturbance, I was astonished to find marked tenderness over the gall-bladder. Being apprehensive about the correctness of the diagnosis I sent for the patient next day. There was no gall-bladder tenderness, but the right kidney was about two inches in front of its normal position. The third pitfall is that an affected appendix may mimic the symptoms of cholecystitis. Why Nature should play these pranks upon a too-confiding physician I do not know, unless the object is to stimulate his mental faculties or to diminish his diagnostic conceit.

To differentiate cholecystitis from duodenal ulcer is always difficult and sometimes impossible. The physical signs may be exactly similar, but the history and symptoms are very important. The two affections may coexist. I think it unwise to trust implicitly in an X ray report, but this may be of considerable value in conjunction with the symptoms and physical signs. An increase in the blood-cholesterin occurs in several diseases, but when the increase is associated with definite signs of gall-bladder involvement it helps to clinch the diagnosis. Appendicitis and cholecystitis occasionally occur simultaneously. Legat's reflex may aid in the differential diagnosis. The reflex is almost always absent in early cholecystitis, but when the appendix reflex is present it is a most valuable diagnostic sign. Vincent Lyon [3] attaches great importance to lavage of the duodenum as an aid to diagnosis. I have no experience of the method. In the chronic variety there is usually a leucopenia with a relative lymphocytoses, but I am not aware of any leucocytic changes in the early cases.

Several writers mention other conditions which may be confused with cholecystitis, but it seems to me that with the exception of neurosis, which may imitate a number of affections, no difficulty need be anticipated. In a case of neurosis with some abdominal discomfort we should investigate the case thoroughly and not pay too much attention to the purely subjective sensations. In these cases an X ray examination is imperative, not only for our information, but also to impress the patient, especially if the result is negative.

Treatment.

It is probable that, as a result of Wilkie's experiments, the bacteriologists may now be able to prepare an effective vaccine for cholecystitis. The only difficulty that I can foresee is that in 14 per cent. of the cases the infection may be due to the colon bacillus or to some undiscovered organism, or the condition may be catarrhal, so that a streptococcal vaccine may be harmful. Perhaps a blood test will solve the problem. We must wait and adopt an attitude of animated expectancy. Meanwhile we can have recourse to therapeutic measures, which experience has proved to be beneficial. The first desideratum is to secure an adequate evacuation of the bowels daily. Secondly, the intake of food should be rigorously restricted for at least a fortnight. Thirdly, the prohibition of certain foods, such as sweetbread, brain, liver, kidney, fatty foodstuffs, veal, animal fats, yolk of egg, and green peas is advisable, but much more important is a semi-starvation diet for a short period. It is amazing how quickly the gall-bladder tenderness disappears when the diet is reduced to a satisfying minimum. The recuperative power of the liver after a well-earned rest is striking. Fourthly, improve the digestion, administer cholagogues—the bile salts being the most effective—and prescribe liver packs. If the blood pressure is even moderately high the needle douche should be omitted. Strong sulphur water is not only a cholagogue but also a powerful intestinal disinfectant. For acidity a useful combination is cremor magnesia and liquor taka diastase with carminatives. Sodii glycocholas, grs. 3, and urotropin, grs. 7, can be dispensed in cachet form, a cachet to be taken night and morning, and these drugs are clearly indicated in this affection. Colalin gr. ¾ (cholalic acid), may be substituted for the glycocholate. Exercise, such as riding, golfing, curling, walking, and bowling, tend to improve the digestion and to increase the work of the liver. Chills and fatigue should be avoided and the use of warm baths daily should be encouraged. Patients do not realise how very important the skin is as an organ of excretion.

After a short period of dietetic restriction endeavour to promote the general nutrition of the patient by the means already indicated. In this connexion remember that nitrogenous food increases the amount of bile salts which provoke the liver cells to greater activity. Finally, try, if possible, to ascertain the cause of the infection so as to prevent a relapse. If a septic focus be discovered, the appropriate remedies should be applied.

SOME ASPECTS OF THE SURGERY OF THE SPLEEN.*

By A. W. SHEEN, C.B.E., M.S.Lond., F.R.C.S.Eng.,
PROFESSOR OF SURGERY, UNIVERSITY OF WALES.

With spleen's dead weight though heavy grown,
In life's rough tide I sunk not down,
But swam 'till Fortune threw a rope,
Buoyant on bladders filled with hope."
(*M. Green, born 1696, died 1737, "The Spleen."*)

Historical Introduction.

A TRIBUTE to Hunter's work on the spleen is only appropriate. Hunter recognised that the organ was not essential to life, described it in over 40 vertebrates, and spoke of accessory spleens. He knew of injury and of enlargement in man. The "General Principles of the Blood" shows how Hunter sought for the solution of problems, many of which beset us to-day. There are nine original spleen specimens of Hunter's in the Hunterian Museum, including rupture, abscess, and cyst in man and normal spleens of various animals.

The case records of Hippocrates contain examples of enlargement of the spleen. In one work of the Hippocratic collection it is said "those persons whose spleen is large have their bodies meagre," which gave rise to Trajan's comparison that the Imperial Treasury was like the spleen, because when that was rich the people were impoverished. Suggestions in Pliny and the Talmud that the spleen was removed in men and in horses to increase their speed find confirmation in the recent work of Macht and Finesilver [1] who, experimenting on rats trained to walk a tight-rope, found that their speed was increased after splenectomy. It is now 300 years since Malpighi successfully tied the splenic vessels in a dog. The operation of splenectomy in man and animals has been performed by many workers in the past and is now being performed for various blood disorders.

Diseases Illustrated.

This oration is based on 17 cases. They include splenic anæmia, Banti's disease, syphilis, leukæmia, purpura, hydatid, unidentified splenomegaly.

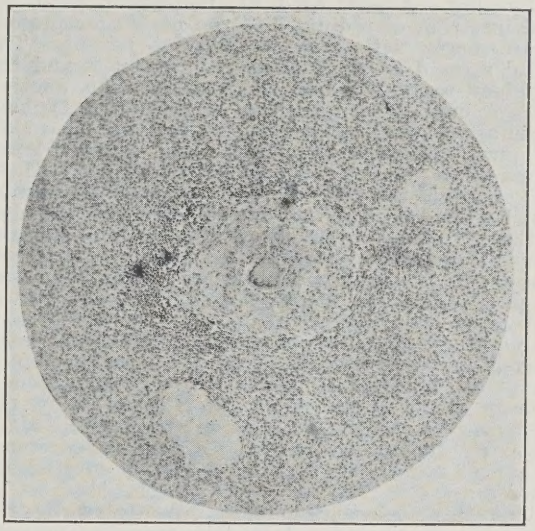
Splenic Anæmia.—In some of my cases who had had hæmatemesis operations had been performed elsewhere under a mistaken diagnosis before they reached my hands. In one case of splenic anæmia, hæmatemesis preceded a demonstrable splenic enlargement, and an early correct diagnosis was made from the blood examination before operation. Recovery, lasting two years, was compatible with liver enlargement, and the blood in the cases described was restored to normal.

[Prof. Sheen then gave the usual signs and symptoms of splenic anæmia, and in reference to its unknown origin emphasised the necessity of investigating the microbiology and toxicity of removed spleens.]

Cases unoperated on terminate usually by passing into Banti's disease, sometimes by progressive asthenia. The term Banti's disease is reserved for the late stage of splenic anæmia with cirrhosis of liver and ascites. While splenectomy does not give such favourable results as in the early disease, recovery often takes place after it, and the liver is restored to normal size. A woman, aged 56, had profound anæmia and profuse uterine hæmorrhages, which ceased with calcium and horse serum. She had all the clinical and blood signs of Banti's disease and her abdomen was tapped twice. Rest and a diet containing liver and orange-juice much improved her condition, and splenectomy was performed with recovery. The spleen was tuberculous, and there was tuberculosis of the liver and other viscera. All cases in this group should have liver function tests performed and the Wassermann reaction taken.

Every case of hæmatemesis or of bleeding from uterus, bowel, or kidney without obvious cause should have a blood examination. The platelet count is important. Rosenthal [2] divides cases into two groups, the *thrombocytopenic*, where the platelets are very low before splenectomy and rise to about normal afterwards; hæmorrhages are marked, and the *thrombocythæmic*, where the platelets are about normal before splenectomy and rise to a very high level afterwards; hæmorrhages are less marked or absent. Splenectomy is satisfactory in the first group but not in the second, in which one of Rosenthal's cases died from mesenteric thrombosis and the others were unimproved and suffered from thromboses in various sites. W. Howel Evans [3] supported Rosenthal's conclusions and recorded a thrombocythæmic case which died from mesenteric thrombosis. He pointed out that coagulation time and clot retraction should be observed; the former is lessened and the latter much more marked after splenectomy.

FIG. 1.



Tubercle of the spleen (× 60).

Fortunately for surgery, the thrombocytopenic appear to be more numerous than the thrombocythæmic class; in my view the latter may be brought into a more favourable condition for splenectomy by the use of an anti-platelet screen or by transfusing the blood of a-cytopenic into a-cythæmic patient. In two of my cases the platelet count has gone up markedly after splenectomy.

According to E. H. Kettle [4] splenic anæmia has no pathological status as a disease. All that can be said at present is that toxic spleens from many causes show evidences of chronic splenitis varying as disease progresses.

Syphilis.—In a case of inherited syphilis after other treatment had failed, the enlarged spleen was removed successfully, and the Wassermann reaction positive at operation was negative three years later, and the patient well. Secondary anæmia and leucopenia were present as in splenic anæmia, and disappeared after splenectomy. Spirochætes were harboured in the spleen.

Myelogenous Leukæmia.—One advanced case, not operated on, had intractable bleeding from a small transfusion wound. In another case the spleen was successfully removed and the patient gained 2 st. in weight, but the characteristic blood condition did not alter and the patient died elsewhere 18 months after splenectomy from cholecystitis and peritonitis.

* Abstract of the Hunterian Oration delivered at the Mansion House, London, on March 4th, 1929. The oration was illustrated by a large number of specimens, photographs, microphotographs, drawings, microscopic and lantern slides.

The important feature in the blood is not enormous increase of white cells, for the case might be aleukæmic leukæmia, but the presence of immature white and red cells. The blood-platelets are usually increased while they are diminished in lymphatic leukæmia.[5] Hæmorrhages in the earlier stages of the disease do not prohibit operation. The spleen often shows infarcts and is largely transformed into myelocytic tissue. Splenectomy at one time was almost universally fatal, but experience at the Mayo Clinic [6] has shown that it can be done with a less than 5 per cent. mortality. But the abnormal blood remains and the eventual outlook is bad.

Purpura.—A girl, aged 21, underwent curettage and insertion of radium into the uterus for profuse metrorrhagia with anæmia, without benefit. The blood showed great diminution of platelets and the capillary resistance test was positive. In another case, a boy of 16, admitted as perforated typhoid ulcer after bowel hæmorrhage, there were also skin purpura, epistaxis, hæmaturia, and swollen knee-joints; the platelet count was high, 680,000. These two cases illustrate that purpura, like splenic anæmia, can be divided into thrombocytopenic and thrombocythæmic classes. Dr. G. A. Sutherland and Dr. Bruce Williamson [7] have given details of the former class. It is purpura hæmorrhagica or Werlhof's disease, and many acute cases tend to natural recovery. The more chronic cases with recurrent hæmorrhages require splenectomy. Epistaxis, small purpuric spots, easy bruising are other common features. The platelet count is low; the spleen is usually slightly enlarged. After splenectomy the anæmia goes and the platelets rise to normal. Mayo says [8]: "In this dyscrasia the effect of splenectomy is almost miraculous and the mortality surprisingly low."

The thrombocythæmic class, illustrated by the second case, includes Henoch's purpura, purpura rheumatica (Schonlein), and anaphylactoid purpura—i.e., where there is urticaria and angioneurotic œdema. The spleen is not usually enlarged, purpuric spots are big. The blood may show secondary anæmia, platelets are either normal or increased. Bleeding time, coagulation time, and clot retraction are normal. Splenectomy is not indicated here with our present knowledge; as with splenic anæmia there is fear of a large rise in the platelet count after operation leading to thrombosis, which may cause death. Mr. C. A. R. Nitch kindly presented me with an enlarged spleen removed by him. The clinical diagnosis was purpura. Before operation there was leucopenia, a low platelet count, and high relative lymphocytosis. These improved after operation. There were no young cells in the blood. Expert histological opinions favoured myelogenous leukæmia, but in that the platelets are increased and there is not a high relative lymphocytosis. The clinical condition did not fit leukæmia of any kind and there was a good recovery. If leukæmia, it was leucopenic leukæmia. Splenic anæmia and aplastic anæmia had also to be considered and the case illustrated well the difficulties of fitting together the diagnostic puzzle.

I would emphasise the necessity of blood examination in cases of unexplained uterine bleeding, and would suggest that miscarriages in healthy young women might be due to blood abnormalities.

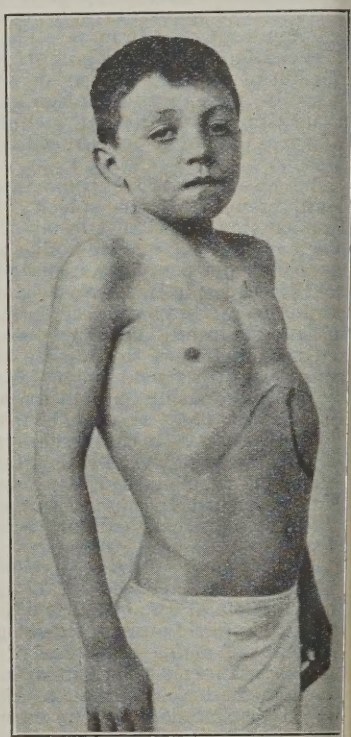
In the secondary purpura of splenic anæmia and of leukæmia, the splenic enlargement is great.

Hydatid.—A cyst in a boy of 12 presented a prominent swelling, and was treated by marsupialisation as the spleen was too adherent for removal. Unexpected death took place from acute double broncho-pneumonia.

Splenomegaly.—In five cases this was the only diagnosis. One with pyrexia which died at home unoperated on was possibly a septic splenomegaly and somewhat resembled kala-azar. [Prof. Sheen spoke of the importance of seeking for protozoal organisms and quoted Fantham and Porter [9] as saying of herpetomoniasis, "disease is in the making to-day"]. Another case died of broncho-pneumonia; the record was incomplete. It might have been leukæmia. Another case presented some of the clinical features of Gaucher's disease; the patient recovered after splenectomy. The spleen was merely a sponge of blood and showed no definite histological picture. The two final cases were in good health, with normal bloods, a negative Wassermann reaction, and no distinctive pathology in the enlarged spleen. They made good recoveries after operation and remain well. Such cases, as knowledge advances, will find their places in a revised nomenclature.

The Blood Examination.—[Prof. Sheen showed tables of blood counts in 15 of the cases. Disappearance of leucopenia and rising platelets were evident in splenic anæmia. The immature cells remained after operation in leukæmia. The method of platelet counting was described. Fallacies resulting from a platelet rise after any major operation had to be guarded against.]

FIG. 2.



Hydatid disease of the spleen showing surface marking of enlargement.

Pathology.—The preoperative diagnosis may have to be revised in the light of the histological findings. The morbid histology is very difficult.

Radiography of the Spleen.—The enlarged spleen can usually be seen in a real "snap-shot." Five radiograms were shown. The syphilitic spleen gives a very distinct shadow. The spleen in a splenic anæmic case distorts the stomach filled with a barium meal. The tuberculous spleen and one splenomegaly give shadows. The shadow of the hydatid cyst shows the line of the cyst wall very clearly.

Radium.—Preoperative radium application to the spleen produces its shrinkage in splenic anæmia and leukæmia, and the blood and general condition improve. The great reduction in the mortality of splenectomy for leukæmia in the Mayo Clinic has followed the use of radium sometimes combined with X rays.[10] I have used radon in a many-curved glass tube kindly supplied by Prof. S. Russ, of the Middlesex Hospital Radon Centre. Marked shrinkage has taken place in two cases, while in two others the spleen did not alter, probably because a large number of applications were required.

Transfusion.—I believe this to be of great value in relation to splenectomy where anæmia is present, and I have carried it out in eight cases—often multiple transfusions before operation, and in four cases a single transfusion after operation. The number of red corpuscles went up greatly.

Preoperative Measures.—Radium and transfusion have already been dealt with. Prof. A. M. Kennedy has shown the great improvement which follows the administration of liver and orange-juice in the diet

Calcium and 5 per cent. lactose are given for a few days before operation. Rowntree and his co-workers at the Mayo Clinic have shown the value of novasurol (or merbaphen).[11] The drug prevents or removes ascites. Liver function is tested before and after its use by noting the rate of disappearance of phenol-tetra-chlorphthalein injected into the blood. In a series of patients with Banti's disease in the Mayo Clinic retention graded 4 was reduced to retention graded 2 when splenectomy was performed with recovery.[12]

The Operation of Splenectomy.—In operating I stand on the right side of the patient and make a left paramedian incision. Adhesions are separated, the spleen delivered, and its bed packed. The gastro-splenic veins are first divided and the main pedicle treated by double clamping and silk ligatures. The operation is often difficult. In one case the stomach was torn, in one the tail of the pancreas injured, and in one clamps had to be left on for 48 hours; all these three recovered and wounds healed without incident. Ten splenectomies were done (excluding Mr. Nitch's case), three for splenic anæmia, two for Banti's disease, one for syphilis, one for leukæmia, and three for unidentified splenomegaly. One of the cases of Banti's disease died. Liver diathermy (Crile[13]) was used in the leukæmia case, to keep the portal blood warm, with apparent benefit. At operation the condition of the liver should be noted.

Summary.

1. Splenectomy is indicated in splenic anæmia (including Banti's disease) and in purpura. Each of these diseases is divided into a thrombocytopenic and a thrombocythæmic class. In our present state of knowledge operation should be reserved for the former class.

2. Splenectomy is of value in selected cases of myelogenous leukæmia, but does not lead to a permanent recovery.

3. After splenectomy for splenomegaly in a case of inherited syphilis the Wassermann reaction was negative three years later.

4. Cases which at present can only be classified as splenomegaly do well after splenectomy.

5. Attention is particularly directed to the necessity of a blood examination in cases of unexplained hæmorrhage from stomach or uterus.

6. All blood examinations when splenectomy is contemplated should include an enumeration of the blood-platelets.

7. The morbid histology of the removed spleen is often difficult to interpret. Preoperative diagnosis may have to be revised in the light of the histological findings.

8. Splenic anæmia (with Banti's disease) may only be a symptom-complex. A case, clinically Banti's disease, proved to be tubercle of the spleen and other viscera.

9. Clinical appearances like Gaucher's disease may not be confirmed on examination of the removed spleen.

10. An X ray photograph will often show an enlarged spleen and such photograph may aid in diagnosis. This is illustrated by a case of hydatid of spleen.

11. Radon applications will produce shrinkage of the spleen.

12. Transfusion is of value as an adjunct to operation.

13. Liver diathermy was used at one splenectomy with apparent benefit.

14. A median incision is recommended for splenectomy with the operator standing on the right side of the patient.

I would like to express thanks to Prof. E. H. Kettle, Prof. J. H. Dible, and Prof. A. M. Kennedy for help to Dr. J. B. Duguid and Dr. J. Mills for valuable help, and to Dr. Owen Ll. Rhys for the X ray photographs.

Clinical and Laboratory Notes.

A NOTE ON CAROTIN AND VITAMIN A.

By Thomas Moore, D.Sc.

(*From the Medical Research Council's Nutritional Laboratory, Cambridge.*)

In 1920 Rosenheim and Drummond published in The Lancet [1] an important communication in which the possible relationship of vitamin A to the carotinoid pigments was discussed. While pointing out that the vitamin could not be identified with any familiar carotinoid they suggested that some unknown pigment might be involved, or that the vitamin might be formed from a carotinoid by the action of light. Although considerable evidence existed to show an association between carotin and the vitamin in their natural sources, the work of Drummond and Coward [2] and of Stephenson [3] showed that crystalline carotin, if carefully purified, was ineffective when supplied to rats as the sole source of fat-soluble vitamins. Interest in the problem was subsequently reawakened by a reference by Drummond, Channon, and Coward [4] to the pigmented nature of cod-liver oil concentrates, but eventually the identification of ergosterol as pro-vitamin D by Rosenheim and Webster [5] gave rise to the speculation that this sterol, rather than a carotinoid, might also be the parent of vitamin A.[6]

In a recent paper by Euler, Euler, and Hellstrom,[7] however, fresh evidence as to the vitamin A activity of the carotinoids is made available. It is pointed out that the earlier work on this subject took place before the separate existence of A- and D-vitamins was realised. Since both these vitamins are now considered necessary for sustaining normal growth it seemed possible that the apparent inactivity of carotin in earlier work might well have been due to the absence from the test diets of adequate supplies of vitamin D. Upon testing crystalline carotin as a source of vitamin A in conjunction with a basal diet adequate in vitamin D, the Swedish workers have in fact observed resumption in the growth of rats on dosages as low as 0·005 mg. per rat per day.

Apart from such direct biological evidence considerable chemical similarities between the carotinoids and the vitamin can be traced. Both the pigments and vitamin resist saponification and are destroyed by oxidation or exposure to ultra-violet irradiation. On treatment with the antimony trichloride reagent, moreover, somewhat similar blue colorations are produced. Euler and his co-workers, realising the importance of this side of the problem, have made these colorations the subject of a detailed spectroscopic examination.

Preliminary experiments upon two samples of carotin, kindly supplied to me by Dr. von Euler and by Dr. R. A. Morton, of Liverpool University, have

afforded support to the claim that this substance may prove active as a source of vitamin A, being effective in sustaining good growth in rats at the minute dosage of 0·01 mg. daily. Although further experiments will be necessary before a definite decision is reached upon the activity or otherwise of chemically pure carotin, it would certainly seem that samples which appear to exhibit all the criteria of purity may exert intense vitamin action. The question next arises as to how this activity may best be interpreted in the light of our available chemical knowledge on vitamin A.

Takahashi,[8] in describing the preparation from cod-liver oil of a concentrate ("biosterin") claimed to consist of pure vitamin A, pointed out some important physical differences by which "biosterin" could be distinguished from the known carotinoids. The former (a viscid oily material considered by Drummond [4] to be highly impure), was characterised by no selective adsorption in the visible region, but displayed a marked band at 320 $\mu\mu$ in the ultra-violet (recently independently confirmed by Morton and Heilbron)[9]; the carotinoids (in general crystalline substances with metallic lustre and high melting-point), on the other hand, were characterised by selective adsorption in the visible and by the absence of marked bands in the ultra-violet. The similarities and differences between "biosterin" and carotin may be summarised thus:—

—	Minimal physiological dose (rat).	Blue coloration with $SbCl_3$.	Selective adsorption—	
			At 320$\mu\mu$ in U.-V.	In visible.
"Biosterin".	0·005 mg. (Takahashi)	Positive	Present	Absent
Carotin ..	0·005 mg. (Euler, Euler Hellstrom)	,,	Absent	Present

Physical properties, therefore, preclude the identity of the classical vitamin A with carotin. Assuming, as the above data would suggest, that the activities of crystalline carotin and of the most potent cod-liver oil concentrates available are of about the same degree, it is obvious that the activity of the concentrates cannot be explained on the basis of such small traces of carotin as may be supposed to be present in them, and conversely that the activity of carotin cannot be explained by the presence of "biosterin" as impurity.

Two explanations may be advanced to reconcile the common activity of sources so different in their physical properties. (1) Both carotin and the classical "vitamin A" may independently possess the same physiological action, or (2) physiological action may be due to an active impurity present in each in amounts so minute as not to affect the physical properties of the materials in bulk.

The first alternative becomes feasible if it be assumed, as Steenbock [10] once suggested, that the classical vitamin A may represent the leuco form of a carotinoid pigment, or if vitamin A activity be determined by some special grouping rather than by an integral molecule, as suggested by Karrer, Euler, and Euler.[11] From a consideration of the extremely small minimal effective dosage of vitamin D, however (less than 0·0001 mg. being adequate in the case of the rat), the second alternative cannot be neglected, since if vitamin A were effective in equally small amounts only about 1 per cent. of impurity in a sample of crystalline carotin would be sufficient to account for its physiological activity. This alternative, however, would entail the non-specificity of the adsorption band at 320 $\mu\mu$, which has recently been shown by Morton and Heilbron [9] to stand in extremely close agreement to vitamin A throughout a wide range of its natural sources, since in carotin this band is absent.

In any case the remarkably high activity of the specimens of carotin cannot fail to be of interest, if only for the reason that they would seem to make the vitamin available in a form comparable in activity with the most active cod-liver oil concentrates that can be prepared. If such high concentration in vitamin A is combined, as would seem probable, with almost complete freedom from vitamin D carotin preparations may prove of scientific value in the administration of vitamin A without the simultaneous admission of the antirachitic factor.

The experiments are being continued.

A CASE OF
TRAUMATIC ANEURYSM OF THE INTERNAL ILIAC ARTERY.

By W. H. C. ROMANIS, M.CHIR. CAMB., F.R.C.S. ENG.,
SENIOR SURGEON TO OUT-PATIENTS, ST. THOMAS'S HOSPITAL
SURGEON TO THE CITY OF LONDON CHEST HOSPITAL.

TRAUMATIC aneurysm of the internal iliac artery is undoubtedly rare. Still rarer is such a case as the following in which it appears to have followed an operation six years before for relief of an ischio-rectal abscess followed by prolonged plugging.

A man of 45 was brought to me by Dr. D. V. Murphy in January of this year. He was thin and neurasthenic and had complained for about six months of pruritus ani and of passage of mucus and thread-worms. For three months he had had a very slight aching pain in the left iliac fossa and left groin, which he admitted was so insignificant as hardly to inconvenience him. Dr. Murphy had examined his rectum soon after this and discovered a pulsating swelling. About October the patient went to a London hospital and was examined manually and by X rays. As the result very largely of the radiographic examination he was told that he had an inoperable sarcoma of the pelvic bones and that nothing could be done for him. Being at the best of times extremely neurasthenic, this made him miserable and depressed. For two months he did nothing, during which time, instead of getting worse, he appeared to get a trifle better and to put on a little weight.

When seen in January he was thin but did not look particularly ill, while he complained of nothing except the slightest abdominal discomfort. On examining his abdomen nothing could be felt, except that there was a vague sense of ill-defined pulsation deep in the left iliac fossa. On examining the rectum, however, a large, soft, pulsating swelling was felt bulging into the left side of the bowel. The pulsation was expansile, and so marked was it that the examining finger could be seen and felt to be pushed up and down at the anus.

It was thought impossible that such profuse pulsation could be due to anything except an aneurysm. Auscultation of the lower abdomen revealed a loud systolic bruit, the Wassermann reaction was negative, and a radiogram taken by Dr. Geoffrey Fildes showed a series of ill-defined, elongated, winding shadows in the pelvis and no signs of bone disease. These were thought to be due to areas of calcification. The patient then admitted that six years before he had had an ischio-rectal abscess on the left side operated on. He knew very little about the operation, except that it took a long time to heal, and both his doctor and nurse had told him that the plugging went in a very long way, at least six inches.

As the aneurysm appeared to be in danger of bursting into the rectum he was strongly urged to have it operated on as soon as possible. It was obvious that nothing could be done from below, and the abdomen was therefore opened by a left paramedian incision. It was then seen that the whole of the pelvis was occupied by a large aneurysm of saccular form, and springing from the side of the left internal iliac artery, which was pushed upwards and forwards by the sac. The internal iliac artery was enormously dilated, being over an inch in diameter right up to its origin from the common iliac. Compression of the internal iliac vessel completely stopped all pulsation in the sac. It was therefore decided to tie this vessel in continuity, and this was done as near the sac as possible without very much difficulty. The patient made an uninterrupted recovery, and three weeks after the operation the swelling in the rectum could be felt to be about half its original size, quite hard and firm, and devoid of any pulsation.

The origin of this aneurysm is, of course, a matter of speculation, but as the patient's Wassermann reaction was negative, and the aneurysm was saccular in form, while there was a perfectly clear history of a deep perineal operation on the same side followed by extensive plugging, the probability seems very strong that in some way the vessel had been damaged or bruised during this latter procedure.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF ORTHOPÆDICS.

A MEETING of this Section was held on March 6th, Mr. NAUGHTON DUNN, the President, in the chair.

Mr. M. SMITH-PETERSEN (Boston) gave a lantern-slide demonstration on

LOW BACK PAIN.

He had tried to look at the problem, he said, in an honest, sincere manner, and invited criticism. He thought the reason why surgeons could not diagnose between lumbo-sacral and sacro-iliac lesions was that they did not analyse the conditions adequately. He showed diagrams illustrating the action of muscles and ligaments in various movements. In a lifting injury, for instance, ligamentous strain might be eliminated. The surgeon must differentiate between ligamentous and muscle strain, for they took very different times to repair, and over-treatment was a common cause of "chronic back pain." If he had confidence in his diagnosis the surgeon could stop immobilisation and start exercise at the right moment. Strain in hyperflexion would sprain muscles first, then ligaments, and would finally cause compression fracture. In lifting, the hamstrings became taut and the ilium was rotated posteriorly, so that the obliquely placed sacro-iliac joints might be involved, the ilium being levered away from the sacrum. The interspinous and articular ligaments could not be involved in any movement that reduced flexion. They were innervated by the spinal nerves, and on this depended the pain located over the peripheral distribution of these nerves. No injury to the lumbo-sacral or lumbar region would cause pain over the distribution of the second sacral nerve. The sacro-iliac joint was practically immobile; the lumbar spine had a good deal of movement. The former was a shock absorber, and the only muscle that protected it at all was the pyriformis. If the hamstrings suddenly became taut, especially if the leg were flexed, there was a tendency to slight displacement of the sacro-iliac joint surfaces, so that prominence was brought against prominence. When the hyaline cartilage was put under pressure in this way traumatic arthritis resulted. The posterior and superior sacro-iliac ligaments were supplied by the first and second sacral nerves, but the innervation of the anterior ligaments was not yet known. On this nerve-supply depended the pain over the lower back and the back of the leg and thigh. It should not be called "sciatica," for only two-fifths of the nerve were involved. The subjective pain corresponded almost exactly with the anatomical distribution of the first and second sacral nerves.

As a man cranked his car he flexed his knee, hip, and trunk and then suddenly tightened the hamstrings, which tended to pull down the ischium and rotate the ilium posteriorly. A woman driving a long, expensive type of car flexed her trunk; then as she pushed the clutch and brake she suddenly tightened the hamstrings. These were two common causes of sacro-iliac strain. Complete relief from sciatic pain due to typical tuberculous infection of the joint had been obtained by operation confined to this joint alone.

The Examination.

The reaction of the patient to each step of the examination must be assessed, and diagnosis must be based on negative as well as positive findings. The examiner must know exactly what he was palpating: kidney, transverse process, lumbar supra- and interspinous ligaments, lumbo-sacral facet, origin of erector spinæ, fourth spinous process, ilio-lumbar ligament, posterior spine, inferior part of sacro-iliac ligaments, superior gluteal nerve, sacro-coccygeal junction, and sciatic nerve-trunk. Tenderness at any of these points would direct the attention to particular sites of possibly injury. Movement should always be tested standing, sitting, and lying. As the patient sat down the hamstrings became relaxed, and when he lay down they relaxed, but gradually became taut as the leg was raised, and leverage was passively transmitted to the pelvic joints. Passive lumbar flexion gave valuable information. *When* pain was caused in examination, and not *how much* pain could be caused, was what gave the examiner the desired information. There was no one pathognomonic sign; diagnosis rested on the history as a whole and the examination as a whole.

X rays were never diagnostic of injury to the sacro-iliac joint; they might confirm a clinical diagnosis only. The X ray appearances varied at different ages, and the surgeon should be familiar with the normal conditions. If one joint looked "older" than all the other joints of the body it would arouse suspicion. The wear and tear of life made the cartilage thinner and hypertrophic changes began to appear. X rays must always be interpreted on the basis of age. The same process of thinning of the cartilage was shown histologically. The changes in the hyaline cartilage in traumatic arthritis were not known, but those of recurring sacro-iliac trauma could be histologically demonstrated, because the cartilage was deliberately removed in treatment. Abnormal calcification, nesting of cartilage cells, and outgrowth of fibrous tissue were found, resembling the "normal" cartilage of much older people.

The Operation of Arthrodesis.

Removal had excellent results and was justified when errors in alignment were diagnosed—for instance, by stereoscopic X rays. Modifications in the operation had been introduced to cause as little trauma as possible. The incision went along the posterior third of the iliac crest and then curved down over the posterior sacro-iliac ligaments. Subperiosteal reflection meant removal of the periosteum in a continuous glistening sheath by a thin osteotome which cut and did not break. Retraction must not be too vigorous; the superior gluteal artery might be torn or the gluteal nerve strained. A "window" was then made in the bone, the cartilage removed, and the plug replaced. The gluteal periosteum and fascia were made to approximate and adhere to the cancellous bone by resecting the iliac crest, and some of the cancellous bone was packed around the "window" in the joint. A series of 100 cases had given complete

success in 88 per cent. and partial success in 8 per cent. In all cases everything possible had been done to relieve the patient before operation. Mr. Smith-Petersen reviewed the four failures and the lessons they taught. One was that the posterior sacral plexus must not be disrespected. Another was that active, progressive, infective arthritis should not be subjected to arthrodesis; the pain was less on the operated side than on the other, but it was not relieved. One of the partial failures showed arthritic changes in the hip-joint after operation, although before treatment the symptoms had been confined to the sacro-iliac joint. The prolonged period of symptoms, with the leg held in flexion, often caused contraction of the gastrocnemius, and exercises should be given to stretch it. There had been one case only of operative infection in the series; this was easily produced if rigid precautions were not taken. Another "partial failure"—a stretched scar with recurrence of symptoms—emphasised the importance of covering up the approach most carefully. The majority of cases got well without operation, and cases for surgical treatment should be selected with caution and care, after all methods of conservative treatment had been consistently tried for many months or even years. One patient had been unable to sit down for meals for 30 years; after operation she could live a normal life as a housewife. Others had had symptoms for 10 or 20 years. Success depended on diagnosis; if diagnosis could not be made for certain it should not be made at all. Practically all the surgical cases had had "sciatica"—first and second sacral pain—and the diagnosis had been certain before operation.

Discussion.

Sir ROBERT JONES related his experience of "backs" in the old days, when treatment had been simple. The first thing had been a little counter-irritation followed by a firm plaster made of pitch and paper. Many patients had responded in five or six weeks; those who did not were regarded as "neurotic," which was almost equivalent to malingering. A "spontaneous" recovery after an injury had suggested the manipulative treatment for obstinate cases. He thought there might be some common factor to all these troubles and that many recoveries might be due to the breaking-down of adhesions. No pain had quite the same intensity as the pain of adhesions. In the early case of spondylolisthesis and tuberculosis there was little pain. Perhaps manipulations failed because they were not thorough enough and fierce enough. He would still try breaking down adhesions before operating. He agreed absolutely that one should not operate unless one was fairly certain of a good result.

Dr. T. STACEY WILSON pointed out that any injury to the spine was bound to be followed by protective muscular contraction, and when the injury was cured the habit of contraction would remain, causing continued pain which could be relieved by rhythmical exercises.

Mr. BLUNDELL BANKART endorsed what Sir Robert Jones had said; these conditions were very common and easy to cure by vigorous manipulation. Lumbo-sacral strain was quite a different condition and hard to cure, as it was difficult to localise manipulations to that joint. The commonest cause of back pain was the functional or neurotic spine; a neurosis was superimposed on the organic lesion in most cases. It had coloured the whole symptomatology, accounted for the wide diversity of manifestations, and had opened the door to all kinds of therapeutic "stunting." It must be taken into account in treatment.

The PRESIDENT said that most cases got better with conservative treatment.

Mr. SMITH-PETERSEN, in reply, said that "conservative methods" included all sorts of exercises and manipulations as well as support by strapping or braces. Everyone must work out his own ideas of supporting belts. If there were evidence of disalignment, manipulation might be tried—first without and then with an anæsthetic. Plaster was not good; it merely caused weakness and strain of the joints above and below. The object of treatment was to return the patient to his normal activity, not to an invalid life in a mechanical support or to a series of recurrences. Sometimes surgeons were apt to call a patient "neurotic" because they did not know enough about him; nevertheless "neurotic backs" did exist. In some cases old-standing cases could, after operation, put aside all the past and live normal lives. If there were pathological changes in the joint, exercises would not cure. Soft elastic tissue allowed displacements to recur and justified operation. In his experience manipulation by experienced osteopathic surgeons did not always cure patients whom operation would relieve.

LONDON ASSOCIATION OF THE MEDICAL WOMEN S FEDERATION.

A MEETING was held at the British Medical Association House on Feb. 26th, Dr. F. HUXLEY, the President, being in the chair. The subject under discussion was

Opportunities for Work for Medical Women Abroad.

Papers were read by Dr. M. E. Johnstone (Canada) and Dr. K. Atkinson (America), and letters on the subject were sent by Dr. Emslie Hutton (Near East) and Dr. M. Hickley (South Africa). Miss L. Martindale and Dr. K. Warren (Uganda) also contributed to the discussion.

Dr. JOHNSTONE spoke especially of the Province of Alberta, where she had been working under the Department of Public Health. Here the opportunities were very good, as there is complete reciprocity in the matter of registrable qualifications, and indeed, at the present moment, the Department of Public Health is advertising for several women district medical officers to go out at once. The work is mainly among the women settlers. The infant and maternal mortality-rate is, at the present, excessively high, owing to the lack of medical facilities. The climate is one of extremes, but is very healthy, and the whole province is in a state of rapid expansion and increasing prosperity. The prospects for Government medical work, or for general gynæcological practice in one of the larger towns are very good at the present time, and will probably improve still further.

Dr. ATKINSON spoke of hospital work in the United States, especially (where her experience was greatest) in Philadelphia and San Francisco. She gave an enlightening account of work among negro and alien patients, and touched on the differences between the British and American hospital systems. She spoke hopefully of the prospects of gaining "interne" posts, and of the value of these, and the possibility of passing to resident appointments from them. Conditions on the whole did not appear to be vastly different from those prevailing in England.

Dr. EMSLIE HUTTON'S message was not encouraging for English women. Over the whole of the Balkan States and Russia there seems to be practically no opening for English women, though for native qualified women there are numerous appointments. A few mission hospital appointments only are open to foreigners, but there is great opposition from officials.

Dr. HICKLEY wrote of South Africa from two distinct points of view—namely, practice in large towns and "up country." The former was hopeful as specialists are rare, and there is always scope for the running of a specialty in connexion with a general practice. She noted, however, that the supply of South African graduates was really sufficient for the needs of the country. Practice in the outlying districts she considered unsuitable for a woman, both on account of the difficulty of transport and the great distances that have to be traversed, and on account of the attitude of the natives.

Mrs. WARREN spoke of her work in Uganda, and implied that there was room for more women, but that up to the present the prospect had not seemed alluring, and practically none had applied. Government work was essential, as private practice does not yet exist, the British population being relatively very small.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

A MEETING of this Society was held at Sheffield on Feb. 22nd, with Dr. G. W. FITZGERALD, the President (Manchester), in the chair.

Specimens and Cases.

Prof. CARLTON OLDFIELD (Leeds) showed a specimen of some fœtal bones and a uterus removed post mortem. The fœtal bones had caused intestinal obstruction.

Mr. N. L. EDWARDS (Derby) described a case of uterine fistula following Cæsarean section.

The patient, aged 25, had had a Cæsarean section performed for obstructed labour in 1923. The convalescence from this was uneventful, no rise of temperature being recorded. A year later the upper end of the wound broke down, discharging a small quantity of pus. The sinus persisted and after May, 1928, menstrual fluid escaped from it at the menstrual periods which were regular. In September, 1928, the fistulous track was excised entire together with a wedge of the anterior uterine wall in which were embedded two thick silk sutures. Sections of the fistulous track show no evidence of endemetrioma.

Mr. Edwards said that the case illustrated the dangers of unabsorbable sutures in the uterine wall. Other members expressed the opinion that it was the method of suture rather than the material used which mattered in ensuring a well-healed uterine scar.

Prof. CARLTON OLDFIELD recounted two cases of ruptured malignant ovarian cysts. Both cases were seen as acute abdominal emergencies. When the abdomen was opened it was found full of "boiled sago"-like material which was mopped out and the ruptured cyst removed. In each case the abdomen was reopened later and the rest of the generative organs were removed. Both patients had had prophylactic deep X rays since operation. One patient remained well for three and a half years, after which she developed symptoms suggesting a recurrence. The other patient had a recurrence a year later in the transverse colon; 15 months after this one in the jejunum; and now, another 15 months later, had one in the roof of the vagina involving the bladder.

Prof. Oldfield invited discussion on the use of prophylactic deep X rays and on prognosis in malignant ovarian neoplasms. Several members expressed the opinion that deep X rays were not without danger and that the prognosis in these cases was not as bad as was usually thought.

Prof. W. FLETCHER SHAW (Manchester) read notes of a case of uterine diverticulum from a patient aged 34, eight years married and sterile.

She complained of recurrent severe pain in the left iliac fossa at the menstrual period. Examination revealed a mass the size of a small orange in the region of the left appendage. At operation this mass was found to be a cystic left ovary and in the left broad ligament a hard tumour of regular outline about 1½ in. long and 1 in. wide; its upper border was about ½ in. below the round ligament and Fallopian tube and in no way connected with either. It was enucleated from the broad ligament by a considerable amount of blunt dissection and the pole nearest to the uterus actually had to be cut out with scissors. Sections show the tumour to have a thick outer muscular coat and to contain a cavity lined with endometrium but with no retained blood. Its relationship to and entire separation from the round ligament and Fallopian tube preclude it from being considered as a poorly developed uterine horn.

Prof. Fletcher Shaw thought it was a diverticulum budded out from the uterine cavity and then shut off therefrom.

Miss FRANCES IVENS (Liverpool) recorded a case of puerperal gas gangrene infection, a report of which will be published in our columns.

Dr. J. W. A. HUNTER (Manchester) read a note on

Hysterotomy.

He pointed out that the term was used both for an incision into the uterine body through an abdominal incision and for incision of the cervix per vaginam. He suggested that the word "trachelotomy" be used for the latter operation and used it throughout his note. Trachelotomy could be used to facilitate the emptying of the gravid uterus either during pregnancy or at full term, when it was usually done during labour. The note dealt with the use of the operation in labour and the cases of failure of the cervix to dilate were divided into two classes: (*a*) those in which the cervix was normal; and (*b*) those in which the cervix was abnormal either in size or consistency. The mechanism of normal cervical dilatation was described and failure of this was noted as often due to premature rupture of the membranes associated with slight disproportion between fœtal head and maternal pelvis. The note dealt with cases where the cervix was abnormal in length or structure (congenitally), or where it was a part of prolapse and the cervix was hard, thick, and fibrous, but not appreciably elongated. The last type was seen in elderly primigravidæ or in multigravidæ as the result of scar tissue formation. The cases might be complicated by premature rupture of the membranes, slight extension of the head or occipito-posterior positions. The patients were usually left for a considerable time to give the cervix a chance of dilating, but eventually their pulse and temperature began to rise. There was often a history of considerable interference and the child might be dead. Recognised methods of delivery had their difficulties and disadvantages. Trachelotomy allowed of clean incisions into the cervix which could be stitched up carefully immediately afterwards and would allow of delivery by forceps or craniotomy. The method described was of one or two postero-lateral incisions from external to internal os, behind the middle line to avoid the cervical branches of the uterine artery. This length of incision prevented it extending further during delivery. If two incisions were decided upon it was important to mark the site of the second before making the first, as after the first much retraction occurs and orientation is difficult. Accuracy of apposition in suture of the incisions was insisted upon.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF MEDICINE.

AT a meeting of this Section on Feb. 15th, with Prof. R. J. ROWLETTE, the President, in the chair, a paper on

Protein Shock Therapy

was read by Dr. V. M. SYNGE. His cases were treated, he said, with two intravenous injections of TAB vaccine, the first containing 100 million *B. typhosus* and 50 million each of paratyphoid A and B, whilst the second, given after 5 to 7 days, contained double the number of organisms. About an hour after injection a rigor occurred with a sharp rise in temperature to 103° or 104° F. There was severe headache, pains and sweating, and sometimes vomiting and diarrhœa. Aspirin and perhaps morphia were given to relieve the pains. In cases which did well the temperature was always normal within 24 hours; if the temperature remained up for 48 or 72 hours there was never any improvement as a result of the treatment. Twelve cases (chronic sciatica, chronic arthritis, persistent muscular rheumatism) were treated. In most there was slight temporary benefit, in some no improvement, and in a few cases permanent cure. Two illustrative cases were:—

1. Man, aged 49, right-sided sciatica for nine years; tenderness along course of nerve, wasting of right thigh;

hip-joint normal. Unable to work for nine months. After treatment pain disappeared and he resumed work. When last heard of 14 months after treatment he was still free from pain.

2. Man, aged 25, left-sided sciatica for four months. After first injection, rigor and high temperature, temperature not normal for 48 hours. After second injection, rigor and high temperature, temperature not normal for 72 hours. No improvement from the treatment.

The method, said Dr. Synge, was not new, and was often unsuccessful, but deserved wider use in chronic sciatica and rheumatic conditions where ordinary methods had failed. Obviously it should not be employed for feeble patients or those with cardiac disease.

The PRESIDENT had never understood why vaccines were the form of protein most commonly employed; a vaccine of TAB, besides its protein content, must contain a certain amount of toxin, and so a certain amount of toxæmia must be produced, a complication which would be avoided by using proteins which contained no toxin.

Dr. PRESTON BALL had treated 15 cases according to the method advocated by Yeoman of Harrogate,[1] and had got very good results. The objection was that the immediate reaction was extraordinarily alarming. He had found the treatment successful where there was profuse sweating immediately after the injection, and where the temperature had come down rapidly. He thought that in the unsuccessful case mentioned by Dr. Synge the result might have been good if more injections had been given. The routine treatment was at least five injections.

Dr. E. T. FREEMAN said he had first used the treatment for cases of chronic urticaria and similar conditions. He had at first used peptone, but now used TAB vaccine. This produced a very rapid effect in a very short time.

He mentioned a case of mucous colitis to whom he had given about twenty injections, and the motions had decreased from 20 a day to 3 a day. The patient had remained well for some months, but then returned to hospital and was given an enema which had started the colitis again, and on this occasion the treatment had not been successful, and cæcostomy had been performed.

In cases of bony involvement he had found that protein shock sometimes alleviated pain, but the results were never permanent. He thought the great objection to the method as a routine was that it was utterly impossible to foretell the result. It was an unpleasant treatment, but if it were possible to know the kind of case that would respond, it might be used more often and with greater assurance.

Dr. G. E. NESBITT said the method seemed to be largely on the lines of malarial therapy of parasyphilitic infections, which he did not think would succeed as a permanent mode of treatment. He asked if Dr. Synge had made any observations on the white cell content in his cases.—Dr. W. G. HARVEY preferred the term "non-specific therapy" to "protein shock therapy." Dr. A. B. CLERY mentioned a case in which pain in the legs cleared up after an injection of TAB.

Dr. SYNGE, in reply, said that he preferred TAB vaccine to other forms of protein because it was standardised, and therefore it was easy to decide on the amount which should be given at each injection. He had not investigated the white cell count in his cases. The treatment was unpleasant, and many patients after one injection refused to have a second; but if improvement did not follow the first, or at any rate the second injection, he thought it meant the treatment was not going to be successful. The method was harmless, and the cures amounted to 20 or 25 per cent., which he thought made it worthy of trial.

Dr. R. E. STEEN read a paper on Congenital Pyloric Stenosis, and Dr. J. H. POLLOCK contributed notes on a case of Hysteria.

Reviews and Notices of Books.

INFANTILE DEFORMITIES.

Diagnosis and Treatment of Deformities in Infancy and Early Childhood. By M. F. FORRESTER-BROWN, M.S., M.D. Lond., Surgeon, Bath, Somerset, and Wilts Central Children's Orthopædic Hospital. With a Foreword by Sir ROBERT JONES, Bart., K.B.E., C.B., F.R.C.S. London: Humphrey Milford, Oxford University Press. 1929. Pp. 199. 14*s.*

As Sir Robert Jones states in his foreword, this book is a lucid exposition of orthopædic principles, written by a surgeon with wide knowledge. It is especially intended for the school doctor, the general practitioner, and all those interested in infant welfare work. The author's work during the war in the treatment and history of nerve injuries is well known, and since the armistice she has made herself equally accomplished in orthopædic work for which she has ample scope at the orthopædic hospital at Combe Down, near Bath, and at the clinics in the counties of which it is the surgical centre. The book differs from other monographs on orthopædic subjects in that it is written in simple language with the single aim of making general practitioners and those in charge of orthopædic clinics thoroughly conversant with the early signs and symptoms of deforming disease, and by the early application of suitable treatment to prevent the obvious and crippling effects of untreated lesions. Every orthopædic surgeon is familiar with cases of, say, congenital dislocation of the hip and knows how long and tedious is their treatment if a good result is to be obtained. Such cases are, however, rarely detected till some time after the child has begun to walk, when changes have occurred which render difficult any anatomical rehabilitation. Yet if the defect of the acetabulum were recognised in the first few months of life cure would in many cases be easy. The specialist has little chance of seeing such patients early, and it is on the general practitioner that the onus of early diagnosis is thrown, more especially since the blame of this developmental defect is apt to be imputed to him in his obstetric capacity.

We commend those parts of the book which deal with defects of posture to our readers, for here the author speaks with authority, having worked under Prof. J. E. Goldthwait, of Boston, and having achieved notable results in her own clinic at Bath. The hints given as to the application of plaster-of-Paris are the valuable outcome of actual experience of difficulties and of the ways of surmounting them. Instruments are sufficiently described and the principles which should guide their prescription clearly stated. The book is well illustrated.

COLLECTED SCIENTIFIC PAPERS OF JOHN JAMES WATERSTON.

Edited with a biography by J. S. HALDANE, M.D., LL.D., F.R.S., Fellow of New College, Oxford. London: Oliver and Boyd. 1928. Pp. 709. 25*s.*

THE prompt recognition of true merit is one of the greatest difficulties in all administrative work. While it is generally believed that this difficulty is less serious in science than in other branches of work, such as literature or art, in which recognition is almost as common post mortem as ante mortem, there are exceptions to this rule. The case of John James Waterston is one of the most striking of these. This scientist carried out much original work of first-class importance, and was, as his biographer says, well ahead of his time in the subjects which he studied. Yet his most important paper—on what is now called the kinetic theory of gases—was refused publication by the Royal Society and lay unrecognised for 46 years until Lord Rayleigh disinterred it in 1891. It is somewhat disquieting to read this paper and to see that what is now regarded as an elementary an

almost obvious theory essential for first-year undergraduate students of physical chemistry was then regarded as too fanciful to publish. Further, Lord Rayleigh's statement that the Royal Society's omission to publish it probably retarded the development of the subject by 10 or 15 years shows the very serious effects of such lack of recognition. Are such instances occurring now? There are many branches of science such as immunology or the study of variation in species in which the need for some really original development seems great. It is interesting to reflect that such developments may have been made already, and refused recognition merely because they were truly original.

Waterston's work was not confined to molecular physics, but included a contribution of more direct interest to medical readers, entitled Thoughts on the Mental Functions. This paper was first published as a book but attracted little attention, and is now reproduced as the first 160 pages of the collected papers. Its value is difficult to appraise owing to the admixture of clear and original ideas that are important, or may be important even though still unrecognised, with a considerable mass that is now discredited, such as phrenology, or elementary pictures of nervous physiology that are now replaced by more detailed knowledge. Waterston himself seems to have recognised that (in 1843) the position of nervous physiology was not sufficiently advanced to make progress in objective psychology at all probable, for after the publication of this book he abandoned the subject entirely and spent his time on physical and chemical subjects, with a few excursions into astronomical calculations. The whole of his published work is here reprinted and Prof. Haldane has rendered a considerable service in thus collecting these papers, not only by ensuring a full if tardy recognition of their author's merit, but also by rendering readily accessible a mass of material that still has value to original workers. The book also includes a memoir of Waterston's life which gives a picture of a brilliant thinker, regarded as a crank by his contemporaries, but none the less making contributions of permanent value to science.

Cœliac Disease and Allied Disorders.

Der Intestinale Infantilismus und Ähnliche Formen der Chronischen Verdauungsstörung. By Dr. G. Fanconi (Zürich). Berlin: S. Karger. 1928. Pp. 202. M.11.

This monograph presents the results of one of the most thorough and detailed investigations which has been undertaken on cœliac disease and disorders associated with it, and it is an important contribution to the literature of the subject. The material consists of over 80 cases seen in Prof. Feer's clinic, and the period of investigation extends from 1911 to 1928. It is recognised that the exact definition of these conditions cannot be drawn with exactitude; the term "Herter's infantilism" is reserved for cases corresponding closely to the recognised type, while "Cœliakie" is applied to the following symptom-complex: large typical stools, prominent flaccid abdomen, hydrolability, retardation of growth, osteopathy, anæmia, and metabolic disturbances such as demineralisation and intermediary acidosis—symptoms which are all referable to dysfunction of the small intestine. The characteristics of each of these symptoms are discussed in turn, with detailed descriptions of the cases and of experimental work carried out by the author and others. A particularly clear and convincing section deals with the exact nature of the osteoporosis and the ways in which it resembles and differs from that of rickets. In estimating the etiology, constitutional inferiority is regarded as the principal factor, while dietetic and environmental influences are also of great importance. Cases in which the latter predominate are classed as "secondary." Dr. Fanconi's treatment, which has given very satisfactory results, originated from an attempt to combat the intermediary acidosis which was revealed by biochemical means. It is for the most part dietetic. The basis of the diet consists of full quantities of fruit and vegetables specially prepared; banana flour is particularly recommended. Sugar and starch are reduced to a minimum; buttermilk and meat are allowed, according to the age. The practical details of this method of feeding are fully set out.

Dr. Fanconi's work is well worth the attention of all who have to treat this obstinate disorder.

Comparative Physiology of Muscular Tissue.

By A. D. Ritchie, M.A. London: Cambridge University Press. 1928. Pp. 111. 7*s.* 6*d.*

The mainspring of physiological research has been inquiry into human mechanisms. Other animals have received attention chiefly in so far as their study threw light on analogous problems in the study of man. More recently there has been a convergence of the work of experimental zoologists and certain physiologists leading to investigations fittingly described as "general physiology," but in few branches of this field has enough material yet accumulated for application of a comparative method to be more than a hope. Owing to the rapid progress in muscle physiology, involving intensive research on frog's muscles, and many researches on the muscles of diverse forms, it has become possible to make comparisons between the variations of function of muscles and the variations of some of their properties in different organisms. Muscles can, for example, be arranged in a series according to their lactic acid content; and it is found that the order in which they are placed indicates also the degree of their activity in normal functioning. If nothing very startling can yet be claimed as the fruit of this method, the halting beginnings of a new science are none the less welcome. Mr. Ritchie is to be congratulated on an admirable presentation of laboriously collected material. The volume is prefaced by a well-balanced and readable account of current views on the physiology of muscle based on the properties of the twitch in frog's muscle, and the thesis is maintained that even such elusive phenomena as "tone" in plain muscle can be interpreted in terms of concepts derived directly from the simple twitch. Conclusions from a series of experiments are the subject matter of this book. The method of presentation will delight the experienced worker, but the absence of detail, such as text-figures, may prevent the beginner from getting quite so vivid a picture of the subject as he might desire. The bibliography is full and carefully selected.

Citizenship and the Survival of Civilisation.

By Sir George Newman, K.C.B., M.D., LL.D. New Haven, Connecticut: Yale University Press; London: Humphrey Milford, Oxford University Press. 1928. Pp. 254. 11*s.* 6*d.*

This volume is based on the Dodge Lectures on Citizenship delivered at Yale University by Sir George Newman last year. The author traces civic growth from the early Greek examples, through the communes of the Middle Ages, and the gilds of later mediaevalism, to the full fledged article of the present day. The ruling end of Greek civilisation, he points out, was the subordination of the individual to the State. The State claimed the entire rights, duties, and life of the citizen, and slavery, infanticide, and the confiscation of women were characteristic of this attitude. The importance of health of body and mind in the individual and in the State is obvious. Unless a person be in good health, the State cannot get the best value for his work, whether he is a boy at school, a labourer on the land, or a craftsman in an industrial centre. This fact holds good in spite of the notable work done by sick men and women, such as Laënnec in our profession and that of R. L. Stevenson and the Bronte sisters, and Mrs. Browning, in literature. Sir George Newman's book has a great deal to say about the present and the future State.

He leads us from Aristotle and Plato to hedonism and utilitarianism, Jeremy Bentham, and the Mills, and so to individualism and collectivism. All his chapters are interesting and show a broad-minded culture; he is at his best in the chapters on disease in history and on the disharmony in the body of man. The chapter on this subject is admirable, and discusses physical disharmonies, neglected physiology, eugenics, maternity, infant mortality, as well as even more abstract conceptions. The chapter on the future expansion of civic mutual aid shows clearly the enormous advance in well-being to the multitude engendered by the modern social services offered by the State. The final chapter is on education in citizenship. Sir George states that another pestilence like the Black Death, or another war like the European War, would probably be the end of Western civilisation; and that preventive medicine and public right are the two—and the only two—answers to physical or social disharmony. The programme here set out may seem to the minds of some at the present time to be Utopian, but those who contrast the health conditions of workers of all ages with those of their predecessors will realise that so much has already been accomplished that the next decade may be even more fruitful.

SPECTROSCOPY OF THE EXTREME ULTRA-VIOLET.

Second edition. By THEODORE LYMAN, Ph.D., Hollis Professor of Natural Philosophy, Emeritus, in Harvard University. London and New York: Longmans, Green and Co. 1928. Pp. 160. 10*s.* 6*d.*

THE second edition of Prof. Lyman's book will be welcomed by all interested in ultra-violet radiation. From the medical point of view this interest is an academic one, for one can hardly hope to make therapeutic use of radiation so easily absorbed by matter that a few millimetres of air can practically quench it. The book gives an extraordinarily interesting account of the methods devised within the last 15 years for the production, analysis, and detection of the extreme ultra-violet rays. These rays are defined by the author as ranging between wave-lengths 2000 and 150 A.U. Beyond, in the sense of shorter wave-lengths, come X rays, which are very easily absorbed, so that no gap occurs in the spectrum such as confronted investigators when the first edition of this book appeared.

This work will prove of the greatest value to those wanting information on the physical properties of extreme ultra-violet radiation.

RADIATION IN CHEMISTRY.

By R. ALAN MORTON, B.Sc., Ph.D. Liverp., F.I.C., Lecturer in Chemistry in the University of Liverpool. London: Baillière, Tindall and Cox. 1928. Pp. 284. 15*s.*

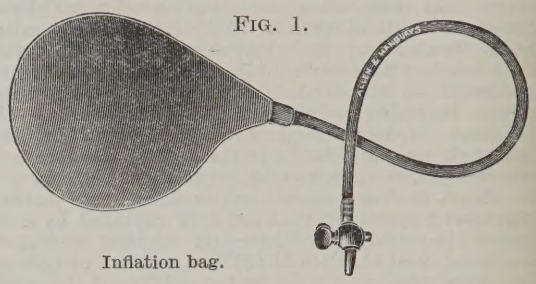
THIS book, which is one of a series designed to give a survey of industrial chemistry, includes within its scope the whole of radiation, ranging from light to X rays. The book is divided into eight sections, each of which is to a large extent self-contained. Mr. Morton has succeeded in producing a book which, though essentially practical, yet shows clearly the theory underlying the processes being described. This is well brought out in the chapters on photographic work, where a description of the processes by which photographic emulsions are prepared is accompanied by a most satisfactory account of the theory of image formation. Section VII., which is devoted to biochemistry and light, travels perhaps unnecessarily far into fields outside the scope of the industrialist. The discussion upon modern light therapy can hardly be of any assistance to the chemist occupied with the irradiation of foodstuffs. On the whole, however, the author has succeeded in presenting information bearing upon chemical processes in an attractive and well-balanced way, and no one will be bored if taken on a few pleasant excursions outside his direct line of work.

New Inventions.

SOME AIDS TO EXCISION OF THE RECTUM.

Inflation Bag.—In carrying out excision of the rectum from the perineum I have found it advantageous to insert a rubber bag into the wound before closing it. The bag (Fig. 1) has a tube and tap attached to it for inflation. The bag is to support the pelvic floor after excision, especially during the first few days, when there is some risk of a hernia

FIG. 1.

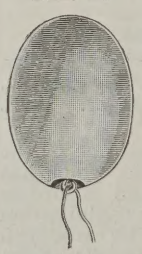


Inflation bag.

in that region if vomiting is severe. It is also useful for the control of hæmorrhage and acts as a drain. The tension can be diminished or increased as required. The bag can be deflated to allow of irrigation of the wound and subsequently inflated. It is usually removed after four or five days.

The Egg.—I have also employed a piece of wood shaped like an egg (Fig. 2), with a small staple at one end to allow of ligature attachment. The egg is pushed into the rectum before the anus is sewn up and tethered to it. During the separation of the anterior wall of the rectum from the male urethra and prostate or from the vagina the egg is pushed forward with the left hand and helps to define the rectal wall. There is often considerable danger of puncturing the rectum during this stage of the operation, and I have found the dummy egg of great assistance.

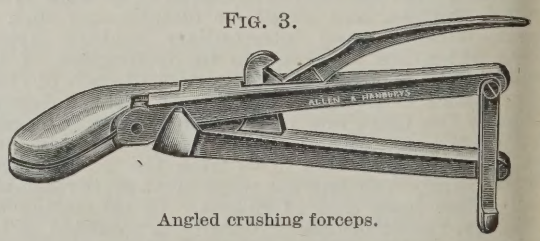
FIG. 2.



The egg.

Angled Crushing Forceps.—The crushing forceps for the bowel which Miles has popularised for the abdomino-perineal operation are often difficult to use satisfactorily in the perineal operation. This is specially so if the growth is a high one and the pelvic colon short when the bowel must be crushed well within the pelvic cavity. To facilitate this stage of the operation I have had a model made (Fig. 3) with the blades set at an angle of 45° with the handle, which allow the bowel to be crushed at right angles to its long axis high up in the pelvis if required.

FIG. 3.



Angled crushing forceps.

These three appliances, which have been made by Messrs. Allen and Hanbury, have been well tested in a considerable number of excisions, and I can recommend their adoption.

C. GORDON-WATSON, K.B.E., C.M.G.

THE LANCET.

LONDON: SATURDAY, MARCH 9, 1929.

A COLLEGE OF OBSTETRICS AND GYNÆCOLOGY.

If ever an undertaking deserved to be described as "an open secret" the scheme for the foundation of a College of Obstetrics and Gynæcology may be thus described. Everyone has known for a considerable period, although so much of the preliminary stages have been conducted with the necessary privacy, that a proposal to form a British College for the advancement of obstetrics and gynæcology, having been under anxious deliberation, has passed into a critical phase; that is to say, the proposals having taken definite shape, the opinion of the existing Royal Colleges was sought and their coöperation requested. The last stage, up to date, was reached when those Colleges manifested a reluctance to support the new movement, although neither of the ancient corporations can be said to have made a more vital objection than that certain of the powers which the new College desired would constitute a trespass upon their provinces. The aims and ideals of the new College were recognised as sound, but the older corporations wanted more proof than they as yet possessed, that it was proposed by the innovators to do anything which they could not do.

The proposal to found the College of Obstetricians and Gynæcologists had for its inspiration many reasons, of which the principal one was the desire to combat maternal mortality, the figures of which are an admitted scandal when the progress of medicine and surgery in every other branch is taken into consideration. Any reform here would imply a better training and a higher standard of examination for medical students in these subjects, with fuller opportunities for learning. Further, the establishment of the College was designed to increase the prestige of this branch of medicine. For it was felt that to secure corporate recognition for a specialty which is both medical and surgical would encourage young practitioners to devote their professional activities to its advancement. Recognising the force of all this we welcome the idea of the College; it will enlist the interest of practitioners in a side of their work and their responsibilities which, in relation to the time spent in its practice, is the most disappointing. There are doubtless disadvantages in the separation of diseases peculiar to women from any other branch of medicine and surgery, but, for good or evil, this distinction is established already, and these diseases have become largely the province of specialists. Further, there may be no need to consider, in the first place, the status of gynæcology, which is only a part of that larger whole—the practice of medicine and surgery; but surely we can all see that the study of obstetrics needs drastic revision. Too many who decide to specialise in diseases peculiar to women regard obstetrics merely as a tedious task which they have to perform until they can afford to refuse to book themselves for any more labours and can spend their days repairing the damage that childbirth still leaves in its train; this may appear cynical, but it is written out of conviction. And a renaissance of the science of obstetrics is overdue. There was a period, not long past, when the mechanism of natural labour was studied intensively, and when great importance was attached to the exact twists and turns induced by the forces acting on the fœtus. Measurements of the bony structure were insisted on, and tiny divagations from the normal, as settled by the interpretation of many figures, were taken into account, even in circumstances where to take such measurements must have been of negligible value. We need not regret the passing into oblivion of some of this lore, but at any rate efforts were being made at that time to reduce maternal and infant mortality by scientific means. When it was found that the mechanism whereby the fœtus reaches the perineum, however well it was understood, was not so easily or safely controlled by outside assistance as had been anticipated, and when it was found that the various diameters of the pelvis gave information which was often belied by trial labour, students and teachers alike became aware that scientific obstetrics was still a dream of the future. The reaction has perhaps been too great, and the modern student is rather sceptical of the value of that part of antenatal care which is not concerned merely with the general health of the pregnant woman. He sees the most confident expert antenatal prophecies belied when he has the opportunity of seeing a case through from pregnancy to labour, and since at the same time he is constantly warned of the danger of interference, he tends to regard midwifery as a subject of which very little is known and in which good fortune more than anything else determines the outcome. That is how we stand.

Meanwhile the maternal mortality figures remain unchanged and the decrease in the infant mortality is perhaps attributable more to our better knowledge of infant welfare than to conditions at or before birth. There is one other factor. Many practitioners say that it is economically impossible for the practitioner to follow out the rules which his teachers impress upon him in the conduct of labours, for he cannot afford the time. And the tragic situation is left to right itself or to get worse. The new College would be expected, if it lived up to its demands for recognition, to take the situation in hand. A Royal Charter is not to be sought, for it could not be obtained while the older Colleges do not approve the undertaking, but the College will be founded under the Companies Act if the Board of Trade is agreeable to the scheme which is being submitted for their approval next week.

HOSPITALS UNDER THE NEW REGIME.

WHEN the Local Government Act of 1929 is added next May to the Statute Book, a new situation will arise fraught with immense possibilities for the health of the people. Voluntary hospitals, in spite of steady development in equipment and number of beds, have admittedly failed to meet completely the needs of curative medicine. The Voluntary Hospitals Commission, before it was disbanded, estimated that at least 10,000 additional beds were required in England and Wales, and although a redoubled rate of increase would have provided these extra beds within about five years, had the means necessary to do so been available, the post-war depression did not allow this to come to pass. Finance has been simplified and facilities improved by coöperative schemes such as the Sussex Provident and the Sheffield Penny-in-the-Pound, and homogeneous areas such as garden cities and garden suburbs have begun to treat with insurance companies with a view to founding hospitals on a mutual basis, but they have not been in time to catch up with the need. Under the new Act the councils of counties throughout the kingdom not only come into possession of all the poor-law hospitals as going concerns, but they also secure the right to maintain hospitals of their own or to subscribe to existing hospitals. This right, as Lord ONSLOW pointed out in his reply to the second reading debate in the House of Lords, has long been possessed by county boroughs, although they have only made use of it in a few cases of special urgency. It would be unfair to prejudge what use the county councils will make of their new powers from the results of these experiments. In taking over the poor-law institutions these councils will have an asset of a very varied character, for, as Dr. H. J. MCCURRICH writes in an essay [1] on the treatment of the sick poor, which appears at an opportune moment, the poor-law medical service is probably the most unevenly administered service in the world. There will be almost unlimited scope in the first and obvious duty of bringing all the transferred institutions up to the present standard of the best of them. The administration of these hospitals and of the new hospitals which will now be founded at the discretion of the councils will be in large measure foreign to their previous experience. While it must not be forgotten that the beds in fever hospitals and sanatoriums outnumber those in voluntary hospitals, and that public health authorities already provide in-patient treatment for a large variety of special purposes, it is, nevertheless, a new era which will be ushered in when the apparatus for both preventive and curative medicine is placed in the hands of the same persons, and no one can doubt that the situation is one which, if rightly guided, will lead to a sounder and better-balanced conception of medical practice.

In the debate to which allusion has been made, Lord DAWSON spoke of the Bill as a great constructive measure which showed vision and far-reaching knowledge. His only concern was for the proper safeguarding of that for which the voluntary hospital has stood in the past. His speech, which may be read on another page, had an epic ring about it. A hospital, he said, is not a building made with hands. It is an organisation; an assemblage of great traditions. The hospital service of this country, as we know it, its efficiency, its flexibility of administration, its public spirit, its warmth of heart, all these have gathered round what is called the voluntary system, which has made British hospitals famous throughout the world. It is these hospitals which have at all times drawn into their service the young man of talent whose ambition it is to get a place in them and who is willing to work for years at a pittance in order to gain experience. In the voluntary hospitals as nowhere else is to be found the atmosphere of knowledge and service. Lord DAWSON'S anxiety is based on the lack of any provision in Part 1 of the Bill to ensure the continuance of this great tradition. He has seen examples of the wrong people staffing hospitals and doing work for which they are neither trained nor suited, and he made a final plea to the Government to introduce a clause making it compulsory for the public assistance committees who will have charge of the new hospital service to coöpt people skilled on the one hand in the administration of hospitals, and on the other some of those whose lives have been spent in doing the work of curative medicine. He commended for the Minister's consideration a plain and straightforward proposal to set up under the chairmanship of the medical officer of health an advisory council of doctors in each district which the council administers. To our way of thinking it is not necessarily the experts themselves who should be coöpted or find places on the public assistance committees, but rather those with proved administrative ability whose work has been closely associated with voluntary hospitals or insurance committees, for it is the lacunæ in the medical benefit under the Insurance Act that will require to be filled in as a first charge on the new scheme. It is, however, essential that the general practitioners of the district who form four-fifths of the medical personnel should have sufficient share in administration to secure their interest and coöperation —an aspect of the subject with which we have recently dealt. Lord ONSLOW, in his reply, offered at once to introduce at the report stage of the Bill a clause designed to impress upon local authorities the desirability of the fullest coöperation with the voluntary hospitals (through committees of the British Hospitals Association) and, when further pressed, agreed to insert words providing that among those to be consulted by the local authorities should be representatives of the medical profession in the district.

[1] The Treatment of the Sick Poor of this Country. Rogers Prize Essay, 1926. By H. J. McCurrich, M.S., M.B., F.R.C.S. Oxford Medical Publications. 1929. Pp. 132. 5s.

THERAPEUTIC STARVATION.

IT has been said with some degree of truth that the starving man is receiving a perfect diet. He is being nourished at the expense of his own reserve stores of all the essential foodstuffs, which, at least during the early stages of his fast, can be called upon in the exact proportions in which they are required, and which, having been already incorporated into his own tissues, must be exactly suited to his needs in the qualitative sense. The term "starvation" covers, however, not only a total deprivation of food, but an insufficiency of any or all of the food elements necessary for nutrition, so that, strictly speaking, no hard-and-fast line can be drawn between the results of undernutrition in the ordinary sense of the word and the symptoms of the food deficiency diseases which are now attracting so much attention. Those engaged in investigating the effects of food deficiencies in animals have, in fact, frequently been misled in their interpretation of results owing to their failure to distinguish symptoms of specific dietetic deficiencies

from those of partial starvation in the ordinary sense of the word. A classical example of such confusion was pointed out recently by S. K. KON and J. C. DRUMMOND,[1] who showed that most of the symptoms commonly attributed to a lack of the vitamin B complex in the pigeon were in reality due to deficient total intake of food. Those who employ restriction of the diet for any therapeutic purpose should always keep before their minds the possibility of unwittingly producing states of specific food deficiency by the vigorous exclusion of particular classes of foodstuffs. In his address to the Medical Society of London, reported in this issue, Dr. EDMUND SPRIGGS laid down the principle that the ideal reducing diet should contain all the usual components of a good mixed diet, restriction being thus practised quantitatively rather than qualitatively. It is not to be denied that the restriction of specific food elements has proved of value in the treatment of individual diseases and we may well hope that with increasing knowledge of the physiological action of particular food elements it will in the future be possible to achieve by this means some measure of control over many morbid processes which at present defy our medical skill.

The commonest indication for a general limitation of food intake is obesity, but as Dr. SPRIGGS wisely observes, in undertaking the treatment of obesity the medical profession should concern itself rather with the associated disabilities impeding the normal functioning of the body as a whole than with the mere æsthetic aspect of the condition. The guiding principle in all reducing cures must be to adjust the energy value of the food ingested so that it is less than the amount of energy spent in the form of heat and muscular work. In the normal individual there appears to be some mechanism which automatically adjusts the expenditure of energy so that within limits considerable excess of food beyond the bare requirements can be taken without leading to any increased storage of fat. In certain types of obesity this mechanism seems to be functioning imperfectly, so that quite severe dietetic restriction has to be practised before any appreciable weight reduction is observed. There are, of course, other cases in which obesity is due purely to excessive indulgence in the good things of this life, and this group can be treated with greater ease and satisfaction, for when their weight has been brought down to the required extent by strict dieting they can maintain it at a constant level while they are taking a normal amount of food. These two groups are not separated by a hard-and-fast line and individual cases are sometimes difficult to classify. It is common knowledge that obesity may appear quite rapidly as the result of some change in the mode of living not obviously related to any alteration in diet or physical exercise. Marriage and childbirth not uncommonly provoke a relatively sudden fat storage in a previously normal individual, or, on the other hand, these same incidents may determine the apparent cure of pre-existing obesity. With our present knowledge it is not possible to predict whether either of the opposing effects will follow a given stimulus, but at least such cases teach us that the metabolic balance-sheet of an individual may at one time register a profit and at another a loss, although there may be no gross voluntary change in the items of expenditure and receipts. In such cases there must be unnoticed variations in the expenditure of energy to account for the gain or loss of weight, provided that the fuel value of the diet remains constant and that the digestive function remains unimpaired; such variations may occur either in the amount of physical work performed or in the amount of heat produced, that is to say, in the basal metabolic rate. In actual practice it is rare to find any definite lowering of the basal rate in cases of obesity. Dr. SPRIGGS points out that the obese person has a relatively small surface area in proportion to his weight, and when this weight, and with it the rotundity of his figure, is reduced, his surface area becomes relatively increased, and his heat loss, which varies with the surface area, is also increased. This principle does not apply to men in all states of nutrition; it has been shown that when a man is wholely or partially starved so that he loses considerable weight and is definitely in a state of undernutrition, his basal metabolism is reduced. It appears that under such circumstances some protective mechanism is called into play which favours the maximum conservation of energy within the body and by this means tends to diminish excessive loss of weight.

The medical profession is becoming increasingly alive to the virtues of prophylaxis and it may therefore be asked whether partial starvation has any part to play in guarding against the appearance of diseases or the exaggeration of symptoms in already existing morbid processes. It has certainly been established that diabetes and obesity are frequently associated, and there can be no question as to the wisdom of enforcing dietetic restrictions on overweight subjects who may have inherited a predisposition to diabetes. Similarly, those afflicted with circulatory disorders are, as a rule, greatly benefited by a wisely directed course of food restriction if there is any coexisting tendency to obesity. On the other hand, it remains to be proved whether the efficiency of a whole nation could be raised by attempts to regulate the average amount of food consumed by the mass of its people. The experiences of the Great War, and in particular of the Central European States, certainly lend no support to the view that a state of chronic undernutrition is compatible with normal intellectual or physical vigour. The truth would seem to be that the energy value of the average man's diet can be varied within certain limits without producing any predictable effects on his weight or physical fitness, so that the most precise calculations as to the number of calories which a man of a given weight and occupation should consume would by no means necessarily lead to his attainment of any given standard of nutrition.

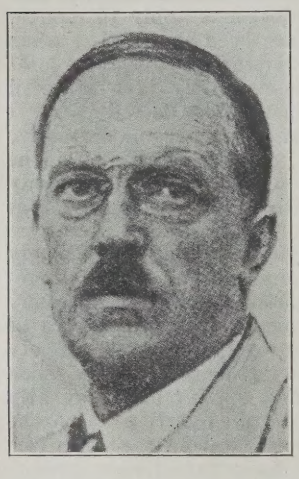
CLEMENS PIRQUET.

THE world is the poorer for the loss of FREIHERR CLEMENS VON PIRQUET who, with his wife, was asphyxiated by misadventure last week in Vienna. His name is perpetuated in a tuberculin test which revealed for the first time the ubiquity of tuberculous infection in an urban community, an achievement in itself sufficient to deserve well of his generation. But PIRQUET—as he preferred to be known without the honourable prefix—was largely responsible for the development of the magnificent children's hospital attached to the University of Vienna, and it was he who collaborated with the British and American relief work in averting the worst horrors of starvation in the youthful population of Vienna after the war. PIRQUET worked out the ration which enabled the Save the Children Fund and the Society of Friends to provide a suitably balanced meal for many thousands of undernourished children at a cost to

their subscribers of only three-halfpence a head. The ideas which inaugurated this development of human physiology may have arisen in the minds of LIEBIG and BUNGE, but the conception of nutrition as an exact science, to which mathematical principles might be directly applied, was something that owed its existence to the enthusiasm and the amazing industry of PIRQUET, whose life was devoted to detailed study of innumerable factors bearing on human nutrition, and more particularly from the exogenous or dietetic point of view. The influence of his earlier work is reflected in the change which took place in current views on infant feeding and nutritional disorders towards the end of last century, the essence of the change being the attribution of increased importance to quantitative considerations. Much that is admirable in the Vienna and Berlin schools of pædiatrics bears the impress of his trend of thought. The opportunity came to test those theories by devising a system of rationing which should utilise the available resources, particularly of fats, with the maximum of efficiency; and they stood the test. Given an adequate supply of protein, the proportion of fat and carbohydrate in the diet was shown to be of little importance, and this principle was made the basis of the official scheme of rationing. It is probable, however, that PIRQUET'S name will be perpetuated, at any rate in this country, rather by the cutaneous tuberculin reaction than by his far more important works on nutrition and *Biometrik*. For the latter, while accepted by experts throughout the world as masterpieces of their kind, must of necessity be limited in the number of their readers by their great technicality and by the knowledge of mathematics which they demand. Whether the "Nem" system of feeding will gain wide acceptance is doubtful, but the mathematical relations which PIRQUET established between simple measurements, such as the sitting height, and nutritional requirements are likely to remain as the sound basis of further research on human nutrition. Prof. PIRQUET had accepted an invitation to read a paper on the prevention and cure of tuberculosis in early childhood before the Section of Diseases of Children at the forthcoming annual meeting of the British Medical Association in Manchester, and his untimely death will disappoint many who would have welcomed the opportunity of seeing in the flesh the virile and attractive personality of the Austrian nobleman, pædiatrist and humanist.



From the Weardale Press.

EXTENSION OF LANCASTER INFIRMARY. — Lord Derby last week laid the foundation-stone of a series of extensions of this hospital which has become inadequate owing to the demands of the wide area which it serves. The scheme, which will cost £75,000, provides for a new children's ward, a maternity ward, the substitution of a permanent building for a temporary structure added during the war, two eye wards, two theatres, extensions to the nurses' quarters, and other additions.

Annotations.

"Ne quid nimis."

THE KING.

AFTER an interval of more than a fortnight without the issue of any pronouncement by His Majesty's doctors the following official bulletin was issued from Craigweil House, Bognor, last Saturday, March 2nd, at 8.15 P.M.: "During the last fortnight His Majesty the King has made satisfactory progress. Weight and strength have increased, and sleep is refreshing. His Majesty is now able to read and apply his mind for short periods of time. We must, however, recall that one of the most anxious features of His Majesty's grave illness was severe exhaustion due to prolonged toxæmia. For this reason careful avoidance of any sustained effort of body or mind will be necessary for a lengthened period, in order to ensure that completeness of recovery which, although still some months distant, we confidently anticipate." The bulletin was signed by Sir Stanley Hewett and Lord Dawson of Penn.

NEW YEAR HONOURS.

THE list of those upon whom it was intended by the Crown to confer recognition upon the New Year's Day of this year has now been published, the delay, of course, being due to the illness of the King. The list is headed, as far as medicine and the allied sciences are concerned, with the name of Sir Berkeley George Andrew Moynihan, President of the Royal College of Surgeons of England, upon whom the signal honour of a peerage has been conferred. Moynihan has devoted his life to building up a school of surgery unique in this country, and in so doing has made a lasting contribution to the pathology of the living. Lady (Florence) Barrett, Dean of the London (R.F.H.) School of Medicine for Women, and President of the Medical Women's International Association, is created a Companion of Honour. The following two medical men have received the honour of knighthood—namely, Dr. Nasarvanji Hormasji Choksy, of Bombay, and Mr. Carrick Hey Robertson, of Auckland, N.Z. In the Order of the British Empire the K.B.E. is conferred on Dr. Charles Hubert Bond, Commissioner of the Board of Control, and the D.B.E. upon Miss Louise McIlroy, professor of obstetrics and gynæcology in the London (R.F.H.) School of Medicine for Women. Sir Walter Fletcher, secretary, Medical Research Council, has been created C.B. The C.M.G. has been conferred on Dr. J. H. L. Cumpston, Director-General of Health and Director of Quarantine in the Commonwealth of Australia; Dr. F. C. Madden, Dean of the Faculty of Medicine in the Egyptian University, Cairo; Mr. A. J. R. O'Brien, surgeon specialist in charge of the Gold Coast Hospital, and on Dr. A. T. Stanton, chief medical adviser to the Secretary of State for the Colonies. Mr. William Thomas Paulin and Mr. Albert Levy receive knighthoods for their services in a lay capacity to the London Hospital and the Royal Free Hospital respectively. Sir Arthur Robinson, Permanent Secretary to the Ministry of Health, receives a G.C.B., and Sir William McCormick, chairman of the University Grants Committee, a G.B.E. Among those created C.B.E. are Lt.-Col. J. K. S. Fleming, Deputy Director-General of the I.M.S.; Miss Frances Ivens, clinical lecturer in obstetrics and gynæcology in the University of Liverpool; Miss Beatrice Monk, matron, London Hospital; Miss Winifred Cullis, professor of physiology London (R.F.H.) School of Medicine for Women and Mr. William Nowell, Director of the Aman Research Institute, Tanganyika Territory. The O.B.E. has been conferred upon Dr. Norman Parsons Jewell, resident surgical officer, European Hospital Nairobi, Kenya, Dr. J. C. S. McDouall, director o Medical and Sanitary Services, Sierra Leone, Mis

Anne Emily Cummins, Lady Almoner, St. Thomas's Hospital, and Miss Isabella Drennan Sandifer, late matron, Ministry of Pensions Hospital, Newcastle; while the following receive the M.B.E.: Dr. Isabella Hardie Curr, Miss Ellen Amelia Cleary, Miss Nora Marie Cremen, Miss Margaret McPherson White, Miss Ethel Mary Cauty, and Miss Helen Cooper Hodgson. The C.I.E. has been conferred upon Lieut.-Colonel Charles Isherwood Brierley, Chief Medical Officer and Inspector-General of Gaols in the N.W.F. Province of India, Lieut.-Colonel Harold Holkar Broome, Principal of the King Edward Medical College, Lahore, Dr. Henry Tristram Holland, missionary in Baluchistan, and Lieut.-Colonel Robert Ernest Wright, professor of ophthalmology, Medical College, Madras. To Mr. Nowroji Jamshedji Bandorawala, P.M.O., Bikaner State; the Rev. Ernest Bell Sharpe, missionary superintendent; Purulia Leper Asylum, Bihar and Orissa; Dr. Pearl Smith Chute, Canadian Baptist Mission Hospital, Akidu, Madras; and Mr. John Hutchison, Church of Scotland Mission, Chamba State, Punjab, the Kaisar-i-Hind medal of the First Class has been awarded for public services in India. The barony conferred upon Sir Berkeley Moynihan is the second received by a doctor in direct reward for professional work and in recognition of the discharge of official duties, and we congratulate him upon his new and high distinction.

EFFECT OF MALARIAL THERAPY ON THE BRAIN IN GENERAL PARALYSIS.

IT is the boast of modern scientific medicine that the rational treatment of disease is replacing the old empiricism. But in the treatment of general paralysis the process has recently been reversed, and an empirical method of treatment by the induction of malaria has come to the aid of the apparently more scientific attempts to kill the spirochætes in the brain by the use of well-established antisyphilitic remedies. When used alone these have proved of little value. As Surgeon Rear-Admiral E. T. Meagher[1] pointed out in a recent discussion at the Royal Society of Medicine, only about 4 per cent. of patients so treated could be discharged from asylums. When to this treatment malarial therapy was added the number who could return to a fairly normal life rose to 20 or 25 per cent. Attempts have lately been made on the Continent and in America to find out the method whereby this cure is effected. For this purpose careful histological examinations have been made of the brains of all patients dying either during or after malarial treatment, and the appearances found in these brains have been compared with those of general paralytics who had not undergone this treatment. The evidence obtained in this way has recently been summarised by R. B. Wilson[2] who himself examined 47 brains in Jakob's laboratory at Hamburg. He found that during the first three to six weeks after the malarial paroxysms there is an exacerbation of all the inflammatory changes in the cerebral cortex. The meningeal and perivascular cell exudates become more abundant, and in addition there is in the earliest stages an accumulation of cells even along the capillaries. There is also an increased number of rod cells and of iron demonstrable by the Prussian blue reaction. After the sixth week these changes recede and gradually very little evidence of inflammation is left except the presence of macrophage cells in the meninges, which are rather evidence of repair than of inflammation. After six months there was in certain cases evidence of recrudescence of the infection; but the brains of these patients did not show the usual diffuse lesions of general paralysis. Instead of this, there were in the cortex and basal ganglia numerous localised inflammatory areas, many of which resembled the early stages of gummatous formations.

These anomalous cortical changes, and the fact that subcutaneous gummata have developed in several general paralytics after malarial treatment, have led to a supposition that the effect of malaria on the disease is to change it from a malignant neurosyphilitic process to a more benign tertiary type. This supposition does not, however, receive Wilson's whole-hearted support. For whereas spirochætes disappear very rapidly from the brain after malaria and were only found by him in one case out of 25 which died in the first six months after treatment, they were found in five out of six brains in which this peculiar relapse had taken place; that is to say, they were as commonly found as in untreated general paralysis, whereas in tertiary syphilis they can very seldom be demonstrated. He considers that no hard-and-fast-dividing line can be drawn between typical general paralysis and tertiary brain syphilis; the two processes tend to merge into one another. But they "represent differences in the relationship between the defence mechanism of the body and the spirochæte."

To sum up the evidence obtained from these histological examinations, it seems certain that malarial treatment, either directly by the pyrexia or by stimulating the formation of antibodies, brings about the death of the majority of the spirochætes in the brain. The toxins so set free cause a severe inflammation of the cerebral cortex, but owing to the absence of living spirochætes this is rapidly recovered from. The process is, in fact, comparable to the vaccine treatment of a chronic indolent affection. After six months or more, if spirochætes remain alive in the brain, they may cause further inflammatory changes, but these tend to be more of a localised tertiary form than of a diffuse general paralytic form and probably respond more readily to ordinary antisyphilitic treatment. This appears to be the practical outcome of these researches, and the necessity for continuing antisyphilitic treatment after the patient has undergone a malarial cure was insisted on by several speakers at the discussion at the Royal Society of Medicine. It seems probable that with fuller understanding and improved technique, the percentage of cures in this country will rise considerably above the 25 per cent. quoted by Rear-Admiral Meagher.

[2] Brain, 1928, li., 440.

RADIUM AND LONDON HOSPITALS.

AT the end of last year Sir Otto Beit offered a sum of £50,000 to King Edward's Hospital Fund to be spent in the purchase of radium for the service of the London hospitals, and at a reception held at the Wellcome Historical Medical Museum last Friday (March 1st) Sir John Rose Bradford set out on behalf of the Committee of the Fund the principles on which the radium is to be allocated. The first question to be determined, he said, was to ascertain what quantities of radium were available in the London hospitals at the present time. In some cases the radium is the property of the hospital, in others it has been obtained on loan, but in no case does any one hospital in London possess quantities approaching in amount to those available at some treatment centres on the Continent of Europe. Even with Sir Otto Beit's gift and the more recent gift of £25,000 to the London Hospital, the quantity of radium at any one hospital will not be equal to that available at some of these centres. Having ascertained the amount of radium at present at the services of the London hospitals, the King's Fund Committee decided to provide a certain number of hospitals with a quantity of radium sufficient to enable them, with their own supply, to function as "radium centres," that is to say, not only to treat their own patients but to be available for a supply of radium emanation to other hospitals; and, further, so far as the amount of radium at the disposal of the Fund permits, to distribute among hospitals coming within the donor's description a supply of radium sufficient to enable them to treat, if not all, a certain number of their patients requiring radium treatment. Some special hospitals have greater need for the use of radium than others; thus, a hospital dealing with diseases of women, or with diseases of the throat, has a greater immediate need than a hospital dealing with diseases

of children. The amounts of radium already in the possession of the hospital have been taken into consideration, and finally, the provision made for the use of the radium and the existence at the hospital of some member of the staff with special and expert knowledge of its use. Three amongst the twelve teaching hospitals already have, or will shortly have, quantities of radium of their own sufficient in amount to provide radium emanation, and these will not at the present moment share in the allocation of the King's Fund radium. In one other case an allocation will be made sufficient in amount with the radium available at the hospital for this hospital also to provide emanation, and thus four radium centres will be available. After the allocation all the teaching hospitals will have quantities of radium adequate to fulfil some, if not all, of their needs. The hospitals have been notified of the provisional allocation, and have been asked to inform the King's Fund of their scheme for the use of the radium, and of the measures they propose to take for the custody of the radium. The radium will be on loan to the individual hospital for a period of one year, subject thereafter to withdrawal on one month's notice. The King's Fund radium is to be available for all hospital patients, both ordinary and pay-bed, but it is not to be removed beyond the hospital precincts without written authority from the King's Fund. Rules for the use and care of the radium are to be submitted by the individual hospitals to the King's Fund, and the Fund is to receive periodical reports from the hospital showing the stocks of radium, the milligramme-hours of use, and the number of patients treated. Sir John Rose Bradford remarked, in conclusion, that much larger quantities of radium than any yet available are required for purposes of research as to the best methods of treatment. In addition to the great cost of radium itself, the cost of placing it in suitable containers for its use in treatment is exceedingly high; hence about a quarter of the outlay is expended, not on the element itself, but on the container and on the expense incurred in placing the radium in the container.

THE ÆTIOLOGY OF ACCIDENTAL HÆMORRHAGE.

ANTE-PARTUM hæmorrhage from premature separation of a normally situated placenta has been recognised for 150 years, and until this century it was assumed that some form of trauma was always its cause. The condition was distinguished from ante-partum hæmorrhage due to placenta prævia by the title "accidental" as opposed to "unavoidable" hæmorrhage, and these names have been retained in this country despite the general recognition that toxæmia plays an important part in its causation. "Toxæmia of pregnancy" is a vague term, and may be used to denote various pathological conditions. Prof. F. J. Browne and Dr. Gladys Dodds[1] have brought forward valuable experimental evidence to show that the one significant predisposing cause of accidental hæmorrhage is chronic nephritis. Their work was the result of observations on a rabbit 20 days' pregnant (corresponding to about six months' pregnancy in man). A culture of *Bacillus pyocyaneus* was injected into the rabbit, and four hours later there was profuse revealed and concealed hæmorrhage. The animal was killed, and on section the kidneys showed not only acute nephritis from the bacterial infection but also an unusual chronic interstitial change. The significance of this chronic change was at first not understood, but later it was discovered that if chronic nephritis be induced in a rabbit by repeated injections of sodium oxalate, the injection of an irritant such as uranium nitrate or *B. pyocyaneus* will bring about accidental hæmorrhage during the second half of pregnancy. In the absence of chronic nephritis, the injection of uranium nitrate or *B. pyocyaneus*, although it produces acute nephritis, is rarely sufficient to cause ante-partum hæmorrhage. In some animals with chronic nephritis, ante-partum hæmorrhage occurred spontaneously during the second half of pregnancy. The functional efficiency of the liver was found to be normal in the experimental animals, and it was also found that in these chronic nephritic rabbits albumin may be absent from the urine between pregnancies and during the early part of pregnancy, only appearing in the urine before the onset of spontaneous hæmorrhage. From their observations, Browne and Dodds think that bleeding is due to accumulation of poisons in the blood which the kidneys are unable to excrete; an alternative explanation is that the kidney has normally a metabolic function, which is interfered with in chronic nephritis. Their work has an important bearing on the so-called recurrent toxæmias of pregnancy, and careful inquiry into the previous history of cases of accidental hæmorrhage will no doubt throw further light on this important subject.

[1] Further Observations on the Ætiology of Accidental Hæmorrhage and Placental Infarction, Jour. Obst. and Gyn., Brit. Emp., 1929, xxxv., No. 4.

THE TRAFFIC IN DANGEROUS DRUGS.

THE report of the twelfth session of the League of Nation's Advisory Committee on the traffic in opium does not vouchsafe very reassuring information. Neither Persia nor Turkey, which between them produce a million kilogrammes of opium annually, furnish any report to the League. The latter State, like Soviet Russia, is, of course, not even a member of the League. Such serious gaps in a conspectus of the world-produce of opium and the commerce in dangerous drugs render the efforts of the Advisory Committee and the Central Control Board largely ineffective. Moreover, one-half of the States which are members of the League, including six which are represented on its Council, have neglected, up to the present, to ratify the Geneva Convention of 1925, and this is said to cause "a grave hindrance" to the League's work in controlling the traffic in dangerous drugs. The new Central Opium Control Board held its first meeting during the sessions of the Advisory Committee, but the relations between the duties of the one body and the other remain to be determined. Illicit traffic in opium, morphine, heroin, and cocaine continues to an alarming extent. Full details are furnished in the report of the recent exposure by the Netherlands Government of a wholesale system of illicit traffic carried on by the Naarden Chemische Fabriek at *Bussum*, whereby enormous quantities of the scheduled drugs imported chiefly from Switzerland and Germany were transmitted for the most part to the Far East. There were thus exported in 1927-28, 950 kilogrammes of morphine, 3000 kilogrammes of heroin, and 90 kilogrammes of cocaine; indeed, it is estimated that this centre of illicit international traffic, now suppressed, dealt with about half the total annual world-production of heroin. The bulk of these contraband exports found their way to China, and the Japanese delegate, Mr. Sato, was justified in his assertion that "it was impossible to deny the justice of the Chinese demand that the flood of morphine and heroin into China should be considered at the same time as the flood of opium out of that country."

RENAL BACK PRESSURE.

THE pathology of renal deficiency associated with prostatic obstruction has long interested urologists and has lately been reinvestigated by H. A. R. Kreutzmann[1] of San Francisco. In the method he employs the first step is to obtain a cystogram so as to determine whether there is reflux into the ureter. If reflux is absent on both sides catheters are inserted into the two ureters and sodium iodide is injected. If reflux is present on one side only a pyelogram is made of the opposite intact side. Kreutzmann finds

[1] Jour. Amer. Med. Assoc., Feb. 2nd, 1929, p. 213–215.

that in long-standing obstruction in which patients show clinical evidence of back pressure, there is often no reflux at all. Where this is so, however, pyelography reveals conspicuous dilatation of both ureters and renal pelves. Even in patients with reflux on one side he demonstrated the presence of dilatation of the upper urinary tract on the side in which reflux had not occurred. The conclusions drawn from his cystograms and pyelograms are as follows: (1) The cause of upper urinary tract dilatation in obstructive lesions of the neck of the bladder and of the urethra in adults is a stenosis of the intramural portion of the ureter. (2) This constriction is due to hypertrophy of the musculature of the bladder. (3) When reflux is present, the increased intravesical pressure tends to keep the upper urinary tract dilated to its maximum. (4) After removal of the urethral obstruction, the wall of the bladder loses its hypertrophy, the stenosis disappears, drainage is improved, and the ureters and renal pelves return to normal. Kreutzmann's explanation of back pressure in the kidneys is, therefore, different from that of Tandler and Zuckerkandl. These investigators laid stress on the anatomical fact that the vas deferens passes in front of the ureters, between the ureter and bladder. They suggested that as the prostate enlarges and pushes up the floor of the bladder the vas deferens remains as a fixed point around which the ureter becomes looped. Amongst reasons why Kreutzmann finds this explanation unsatisfactory is his observation that relief from back pressure is always gained by the use of an indwelling catheter. If the ureteral obstruction were due to the pull of the vas on the ureter such relief would not be expected. Moreover, Tandler and Zuckerkandl's explanation could not possibly apply to cases of median bar formation without general enlargement of the prostate and to obstruction from urethral strictures, as in those cases there is no change in the relation of the vas to the ureter.

THE ROMANCE OF INDUSTRIAL MEDICINE.

THERE can be few more romantic chapters in the tale of human advance than that of the inception and growth of medicine in industry, and Sir Thomas Legge made an enthralling story of his "Thirty Years' Experience of Industrial Maladies" in three Shaw lectures to the Royal Society of Arts, ending last Monday. The most exciting day of his life, he said, was that on which he was able to connect posterior cortical cataract with the exposure to glare in a glass-blowing factory. Yet in that he was only confirming the observations of a half-blind trade-union official. Among 513 glass-blowers he found that 64 had cataract in the right eye and 72 in the left; among 278 workers not exposed to glare, 14 had it in the right and 13 in the left. The left eye of the glass-blower is more often turned to the "glory hole" than the right, so the inference of occupational disease was obvious. The proof was yielded by an investigation into the incidence of cataract among Hearts of Oak members—0·6 per cent.—and among the Yorkshire Glass Bottle Makers' Society—30 per cent.—and the North of England Glass Bottle Makers' Society—66·6 per cent. Sir William Crookes threw himself into the problem with immense enthusiasm, and at last succeeded in finding a glass which would cut off the injurious rays. But here, at once, is an example of one of Sir Thomas Legge's two cardinal precepts of industrial medicine; unless you can bring something external to bear on the workman—something over which he has no control—you will not succeed. For the workmen soon got tired of wiping their sweat-fogged spectacles, and Crookes lenses were little used. Then came the "something external" with the perfection of an automatic bottle-maker, which gathers up the molten glass, and blows it into bottle shape at the rate of 40 a minute, enabling three men to do the work of forty. A delightful coda to the story is the fact that the odd 37 men were not thrown out of work, for the machine, with all its magic powers, failed to insert the glass marbles into ginger-beer bottles, and the human hand was still needed for that. Trade-union officials have helped in many other departments of industrial medicine. It was a secretary who demanded of a professor of botany in Liverpool what it was in African box-wood that made the shuttle-makers mazy and sleepy at their work. With the help of Prof. Sherrington, an alkaloid powerfully depressant to the heart was isolated from the wood and *Gonomia kamassi* poisoning was scheduled as an industrial disease. It is a rare one now, for the publicity of scheduling it led to the substitution of other woods in the shuttle industry. A trade-union officer, again, first drew attention to the skin cancer of the briquette-makers. Miners' ailments account for 90 per cent. of the cases receiving compensation for the 36 scheduled diseases; nystagmus, beat hand, beat elbow, and beat knee, together with silicosis, by many hundreds head the list of cases receiving compensation. Nystagmus alone costs over a million pounds in compensation, for about 1 per cent. of our million miners have nystagmus. We compensate always; some continental countries do not compensate at all, others only if there is total incapacity. Sir Thomas Legge upheld the views of J. S. Haldane, that the disorder is due to the strain—ending in psychoneurosis—of having to look at the black coal face, which absorbs over 90 per cent. of the light that falls on it, and that men might well be better continuing at work than worrying over their eyes above ground. For nystagmus no remedy is as yet in sight. Next in order of frequency come lead poisoning and dermatitis, and these at least are preventable by care. The trouble is that too many workpeople demand cure when cure is impossible, and will not ensure prevention when prevention is easy. Sir Thomas Legge illustrated vividly how familiarity breeds contempt, and emphasised his second maxim: unless and until the employer has done everything in his power, the employee can do nothing to protect himself. How far that "can" should read "will" is perhaps open to argument, but the fact remains nevertheless true. Several kinds of industrial disease, such as trinitrotoluene poisoning and grindstone silicosis, are fine examples of what can be done to protect workers by the coöperation of scientific investigators and employers, but others remain almost unaltered during many years. New risks are appearing with every new industry; when the Commission sat, poisoning by manganese and tetrachlorethane were unknown. Mr. Ben Tillett, the chairman, hoped to see the time when names like Haldane and Collis were more revered by the workers than that of any politician; Sir Thomas Legge looked to the day when there should be no industrial disease. The one might well be the means of bringing about the other. Meanwhile there is a wide field of urgent work for all concerned.

INFECTION IN MULTIPLE ARTHRITIS.

RELATIVELY few cases of multiple infective arthritis are due to specific infection, gonococcal, luetic, or tuberculous; in the great majority no specific germ can be found. Cultures from the synovial fluid and periarticular spaces of infected joints rarely yield positive findings; cultures from the blood, even when taken during febrile attacks, are usually negative. L. G. Hadjopoulos and E. Burbank [1] ascribe this non-success to the presence of antibody in the blood, and state that by neutralising this antibody they have obtained positive cultural findings in 29 out of 145 arthritic cases. In 15 cases streptococci were obtained; these were injected into rabbits, guinea-pigs, and mice, and after one or two months joint swellings took place. X ray photographs of the affected joints show atrophy of cartilage and periarticular infiltration of the soft tissues. No deaths occurred, so that no histological data are available, and until more convincing evidence is

[1] Journal of Bone and Joint Surgery, 1927, ix., 278.

adduced judgment will naturally be reserved. In the absence of any discoverable virus around the joints or in the blood, lesions in distant foci have come to be regarded as likely sources of infection, and clinical bacteriologists are largely occupied with the culture of bacteria and preparation of vaccines from reputed foci. It is true that the finding and removal of an infection in tonsil or teeth or elsewhere may not cure or influence the course of the complaint. In a series of cases observed at the Mayo Clinic, J. G. Meisser and S. Brock [2] found more than half the patients studied had had certain foci removed before coming to the clinic. In many instances there are several foci to be discovered and eliminated before arrest or improvement in the disease takes place. While all such foci may not be relevant, their removal, although having no direct effect on the progress of the disease, may act indirectly by improving the general health.

THE PATHOLOGY OF ANÆSTHETIC FATALITIES.

FEW kinds of post-mortem examinations are so disappointing as those that follow a death under anæsthesia if the anæsthetic has really been the cause of death. It may be truly said that the more the anæsthetic has done towards bringing about the death the less will be the post-mortem evidence. In a death purely due to an anæsthetic—in the rare case in which a normal person dies from an anæsthetic before being operated on—there is probably no morbid appearance to show the pathologist how death was caused. On March 1st Dr. Gerald Slot demonstrated to the Section of Anæsthetics of the Royal Society of Medicine how very small a proportion of the cases investigated as deaths under anæsthetics belong to this category—how few, indeed, of these cases, although deaths *under* anæsthetics, are deaths *from* anæsthetics. He divided the numerous cases which he had investigated into five groups: (1) status lymphaticus; (2) death due to a definite anæsthetic accident (e.g., wrong adjustment of a Junker inhaler); (3) death due to myocardial affections, arterio-sclerosis, &c.; (4) death due to the grave condition of the patient before operation (e.g., advanced peritonitis); and (5) asphyxial death. Only in Class 2 can the mortality be definitely attributed to the anæsthetist. In many cases Dr. Slot found that surgical shock was the chief factor; in others an unsuspected pulmonary embolism had been found, or acute pulmonary œdema or coronary thrombosis. He devoted a good deal of his paper to status lymphaticus, laying down definite and incontrovertible appearances that must be present post mortem to justify the application of the term. He had no doubt at all of the existence of the condition, which was sometimes found, quite apart from anæsthetics, as the sole explanation of a sudden and unexpected fatality. As a preventive measure for patients in whom the condition was suspected beforehand Dr. Slot believed efficient calcium administration to be probably of real value. Oral administration, unless in large doses on an empty stomach, was almost useless and the intravenous route should be employed. Dr. Slot alluded to necropsies which he had made on patients who had died after a spinal anæsthetic. There again the findings, qua anæsthetic, were entirely negative.

A GIPSY ENCAMPMENT.

CROWBOROUGH, in Sussex, has long been suffering from the presence of a large gipsy encampment, which has caused a good deal of annoyance to residents in the locality. Though from time to time there have been serious feuds among the gipsies, resulting in various charges before the magistrates and even higher tribunals, the main complaint against them arises from the insanitary condition of the piece of common land they occupy. Repeated attempts have been made to force these gipsies to provide sanitary conveniences and to abate nuisances, but notices served upon them have not been taken seriously. Without proper water-supply, or facilities for the disposal of refuse, and without any sanitation at all, their area not only has become unfit for human habitation, but is also an offence to all who live near the camp. The sanitary authority—in this case, the Uckfield Rural District Council—has always a difficult task in dealing with such people, for they often threaten violence against any official who is unaccompanied by police officers; but at Crowborough the magistrates are supporting the authority in the hope of bringing about a better state of affairs, and ridding the town of what is described as a menace of many years' standing. The Council have taken proceedings against the gipsies, and at Mark Cross Petty Sessions on Feb. 26th no fewer than 17 were summoned for being the owners of vans, tents, and similar structures, and allowing them to be used in such a way as to be a nuisance or injurious to health. The magistrates, under provisions of the Public Health Act, 1925, made an order prohibiting the use of vans, tents, and structures for human habitations in the area, and gave the gipsies two months in which to quit. The gipsy problem is a big one, and always bristles with difficulties arising from their customs and habits, to say nothing of their view of the law. With the decline in horse-dealing and other nomadic arts, an increasing number are settling down to the ordinary life of the towns. Those who still follow the vagabond life are most popular with the public health authorities when they are moving to somewhere else, and where they cause a standing nuisance there is a growing disposition to deal with them peremptorily and exercise to the full the ample powers provided under the Public Health Acts.

WE have just received a copy of the Medical Register for 1929, which contains the names and addresses of the 54,252 persons entitled to practise medicine and surgery under the Medical Acts of 1858 and 1886, an increase of 661 over the number of names in the previous year. During the twelve-month 859 names were added by registration in England, 404 in Scotland, 217 in Ireland, 168 to the Colonial List, and 8 names to the Foreign List—1656 in all. During the same period 1038 names were removed from the Register, 845 on evidence of death, 1 on ceasing to practise, 4 as the result of disciplinary action by the General Medical Council, and 188 who failed to respond when desired to do so by registered letter. Fify-four names were restored to the Register during the year. The 102 preliminary pages of the volume, which contain warning notices and summaries of the Medical and Dental Acts remain unaltered except for the omission of the Province of Quebec from the list of British Possessions qualified to grant degrees registrable in the Colonial List. This table is dwindling from year to year as the Canadian Provinces fail to reciprocate. Japan and Italy remain the only foreign countries whose degrees are still registrable in the Foreign List.

THE Oxford Ophthalmological Congress will assemble this year at Keble College on Wednesday, July 3rd, and meetings will continue until the 6th. On Thursday Prof. Joseph Meller, of Vienna, and Dr. J. S. Fraser, of Edinburgh, will open a discussion on Diseases of the Lacrymal Apparatus; on Friday morning Miss Ida Mann will deliver the Doyne Memorial Lecture, her subject being the Vascularisation of the Vertebrate Eye; and on Friday afternoon a discussion on Ocular Manifestations found in Fractures of the Skull will be opened by Mr. Hugh Cairns and Mr. Charles Goulden. Further particulars may be had from the hon. secretary of the Congress, Mr. C. G. Russ Wood, 12, St. John's-hill, Shrewsbury.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XXV.—REPORTS ON MATERIAL CURETTED FROM THE UTERUS.

THE interpretation of material curetted from the uterus is sometimes difficult, especially when carcinoma of the body of the uterus is suspected or a possible recent abortion has occurred. The operation is performed for a variety of reasons—for diagnostic purposes, to remove retained products of conception, to elucidate and cure cases of unusual hæmorrhage. In most cases something is removed which may present characteristics easily recognisable by the naked eye, but often microscopic examination alone reveals the true nature of the material. As it often happens that the future treatment of the case depends upon the verdict pronounced after a microscopic investigation, it is important that this verdict should be definite, not ambiguous, and, above all, correct. An indefinite report on curetted material is worse than useless; for instance, it is not unusual to receive a report like the following: "This material shows glandular elements and stroma, the former showing much irregularity in outline and active cell proliferation. Although these appearances are not typical, a malignant growth cannot be excluded." Such a report as this, only too common, lands the surgeon in a dilemma from which he finds it hard to extricate himself or to do justice to his patient. Usually he decides to take no risk of missing a carcinoma of the body of the uterus, and so performs a panhysterectomy, only to find no evidence of growth after removal! As a proof that this is no exaggeration a recent experience of my own is worth recording. A few weeks ago sections of curetted material from five patients were submitted to me for confirmation; in all of these a carcinoma of the body of the uterus had been diagnosed, in three a hysterectomy had been done, and in the other two this operation was contemplated. All the sections showed simple thickening of the endometrium, and in none of them was there any evidence of a malignant growth. This is not by any means an isolated experience and must be happening frequently in all parts of the kingdom. The curious point is that, in my experience, the opposite hardly ever occurs—namely, that a malignant growth is mistaken for a simple condition of thickened endometrium.

The Collection of Material.

The reasons for these mistakes more often lie in the character of the material sent to the pathologist than to imperfect knowledge on his part of uterine histology. Only too often curetted material is improperly preserved, the sections are badly cut and stained, and are not even properly cleared before they are mounted. Realising that uterine histology is difficult at all times, proper preservation and the best sections possible are essential if the pathologist is to have a fair chance of making a correct diagnosis. All fragments should be collected *free from blood* and placed in fixing fluid, preferably 10 per cent. formalin in normal saline solution, but failing this, undiluted methylated spirit does very well. Fragments left soaking in blood and serum for 24 hours become macerated, epithelium is shed, nuclei lose their staining properties, and the specimen is hopeless from the pathologist's point of view. I have seen fragments sent through the post merely folded in paper, like a powder, so that on arrival they are quite dry, hard, and sticking to the paper.

The Naked-eye Characters of Curetted Material.

Thickened Endometrium.—If thickened endometrium is removed with a sharp curette, pinkish-grey gelatinous *strips* from one to two inches long appear. They are usually about 3/16 in. wide and vary in thickness from 1/16 in. to ¼ in. These are easily made manifest by placing each curette-full upon a sloping towel, when the blood will run away and leave the strip of mucous membrane unencumbered.

Carcinoma.—When, on the other hand, fragments of carcinoma are removed, the curette brings away masses of material which have the consistence of a ripe pear, and which fill up the eye of the curette more or less completely. *There are no strips.* It sometimes happens where the growth is small that only minute fragments are removed, and these should always be regarded with suspicion because they *are* fragments and not gelatinous strips. These remarks apply equally to the curettage of a squamous epithelioma of the cervix and to that of a columnar-celled carcinoma of the body of the uterus.

Chronic Metritis.—In cases of chronic metritis of the subinvolution type the endometrium is usually not thickened and the curette removes very little except pulverised débris. This applies to cases of long-standing chronic metritis, years after childbirth and usually after the age of 40 has been reached. In cases of recent subinvolution following abortion or full-time labour, thickened endometrium, brought away in strips, may be all that is found.

These three classes of cases comprise the great bulk of the curettages performed for diagnostic purposes in women round about the menopause, and it will be seen that the naked-eye appearances of the material removed are usually quite characteristic and do not require microscopic examination except for purposes of confirmation. One axiom in this connexion cannot be too strongly emphasised, and that is that carcinoma of the body of the uterus practically never occurs until after the age of 45, or until after the menopause, and that carcinoma of the body of uterus diagnosed in a woman below the age of 45 should be regarded with grave suspicion, and no radical operation should be performed until the diagnosis has been confirmed beyond all question. Let it be remembered that there is never any urgency to perform a hysterectomy for carcinoma of the body of the uterus; the growth is slow-growing, the prognosis is good, even if symptoms have been present for months. The delay of a week or two will make no difference to the outlook for the patient.

Products of Conception.—When curettage is performed for the removal of suspected retained products of conception, narrow-bladed swab forceps should be used before the curette. These should be passed up to the fundus, then withdrawn half an inch and opened as widely as the uterine cavity will permit. When closed again the forceps will often grasp a fragment of placenta, a placental polypus, or old adherent blood-clot. This, when removed, has certain characters which usually reveal its nature. The material is fleshy and peculiarly coloured; part of it may be purple, part crimson, and part yellow. These colours are practically never seen in any material except retained products of conception. The microscope will confirm the diagnosis by revealing chorionic villi, decidual cell masses, fibrin, and blood-clot.

Chorionepithelioma.—In the very rare instance of the occurrence of a chorionepithelioma following hydatidiform mole, abortion or full-time labour, the curette is a dangerous instrument on account of the copious hæmorrhage which follows its use. Nevertheless it has to be used for diagnostic purposes, and the only safeguard is rapidity in operating, followed by immediate tight plugging of the uterus. The material removed looks like blood-clot and is often offensive from decomposition. Only the microscope will reveal a small area containing the new growth. The use of swab forceps before curetting is advisable in cases other than those of retained products of conception. They will often bring away an unsuspected polypus from the body of the uterus, particularly in cases in which there has been irregular intermenstrual bleeding as well as menorrhagia. The curette may miss a polypus, but the swab forceps very rarely does so. It is often taught that the

uterus should be explored by the finger before curettage, but this is rarely possible or advisable except after recent abortion or labour. It is practically impossible to dilate the cervical canal sufficiently to admit the finger without lacerating the internal os. The latter occurrence is not devoid of danger since very severe hæmorrhage has followed it, to say nothing of the risk of infecting the parametric cellular tissue.

The curette will not remove small submucous fibroids, but will always reveal their presence. As they project into the uterine cavity the curette gives the sensation of bumping over them. Also, the curette will sometimes reveal a fibroid in process of extrusion and becoming polypoid, by passing up by the sides of it at one time or impinging on its lowest portion at another. These findings, combined with a careful bimanual examination, will usually reveal whether more than one fibroid is present, and will assist in deciding upon future treatment, whether the tumour can be removed by vaginal myomectomy, abdominal myomectomy, or hysterectomy.

Microscopic Appearances of Curetted Material.

It is hardly possible here to enter fully into the histological appearances of all the tissues met with during the operation of curettage, but a few points may prove to be of interest and value.

Thickened endometrium, whether due to the normal changes brought about during the menstrual cycle, or to pathological changes such as result from infection or recent subinvolution, presents a great variety of appearances and constitutes the chief difficulty in the study of sections of curetted material. The glands vary enormously in size, tortuosity, and in the appearance of their lining epithelium. In the menstrual thickening the glands are regularly tortuous, dilated and filled with secretion, whilst the stroma cells are enlarged and resemble miniature decidual cells. They are, however, never as large as the true pregnancy decidual cells. The gland epithelium is very regular, always in a single layer on a basement membrane. In pathological stages, the so-called endometritis, much greater complexity of the glands may occur. They may exhibit great irregularity in shape and size, sometimes being locally dilated and cystic. In recent abortion cases, without obvious retained products of conception, the great irregularity of the glands constitutes the chief pitfall in uterine pathology. They are often mistaken for the alveoli of a columnar-celled carcinoma and wrongly diagnosed as such. This mistake, however, should not occur, because a careful scrutiny will show that everywhere the epithelium is in a single layer, always on a basement membrane, and that there is no uterine muscle in the fragments to indicate that infiltration of the uterine wall has occurred. Further, if it be remembered that carcinoma of the body of the uterus almost never occurs before the menopause that fact alone will prevent a hasty and erroneous diagnosis.

Cervical polypi removed by the curette are really small adenomata composed of glands, connective tissue, and blood-vessels. They occasionally present puzzling appearances near their lowest pole, where they hang down into the vagina. At this point there is a tendency for their normal columnar epithelium to undergo metaplasia to a squamous type, and when seen near the orifice of glands sometimes gives a spurious appearance of dipping down into the stroma. This quite normal and harmless change is often diagnosed as an early squamous epithelioma, and a hysterectomy is done or advised. Mucous polypi of the uterus never under any circumstances become malignant, but, of course, a malignant growth may commence near by and destroy them.

Retained products of conception are easy to recognise, being composed of chorionic villi, decidual masses, and blood-clot. There are, however, certain cell elements seen in sections of uterine mucous membrane after recent abortions or full-time delivery, which raise a suspicion of chorionepithelioma. These cells are large, multinucleate, and often degenerate, usually single and associated with necrotic debris. They really represent fragments of syncytium from necrotic villi and are quite common appearances.

Chorionepithelioma is only to be diagnosed when definite masses of active syncytium and rapidly proliferating Langhans cells are seen in juxtaposition, invading uterine wall on one side and leaving a trail of blood-clot and debris on the other.

Decidual masses alone may be removed by the curette, without any villi; in such a case it is impossible to say, from the microscopic appearance, whether the pregnancy has been intra- or extra-uterine.

Conclusion.

In the presence of actual malignant growths such as squamous epithelioma of the cervix or columnar-celled carcinoma of the body of the uterus, it cannot be too strongly emphasised that it is the general appearance rather than upon individual cell elements upon which the diagnosis is based. Cervical cancer is so typical that it can hardly be overlooked, but it must be remembered that the commoner forms show very few, if any, cell-nests or keratinoid changes. In columnar-celled carcinoma it is the extreme complexity of the epithelial alveoli, the irregularly proliferating epithelium often in more than one layer, the presence of many mitotic figures in the nuclei and, above all, the presence of smooth muscle and fibrous tissue in the growth indicating invasion of the uterine wall which serve at once to establish a diagnosis.

Amongst rare growths discovered by the curette, sarcoma is found occasionally, round-celled, spindle-celled, or mixed-celled, and is generally quite obvious. In any doubtful case, Van Gieson's stain will usually demonstrate at once the presence or absence of fibrillated connective tissue and smooth muscle, and will thus enable a fibromyoma to be distinguished from a sarcoma.

Obstetric Surgeon, St. Mary's Hospital; Surgeon, Hospital for Women.

The Services.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lt. (D.) A. C. Bloomer to be Surg. Lt.-Comdr. (D.).

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. H. J. Crossley, having attained the age for compulsory retirement, is placed on ret. pay.

Maj. C. W. O'Brien to be Lt.-Col, vice Lt.-Col. H. J. Crossley.

Temp. Capt. C. I. Hannigan relinquishes his commn.

E. J. Curran to be temp. Lt.

ARMY DENTAL CORPS.

Lt. W. McAndrew to be Capt.

REGULAR ARMY RESERVE OF OFFICERS.

The undermentioned, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.: Col. E. T. F. Birrell, late R.A.M.C.

TERRITORIAL ARMY.

Capt. A. H. D. Smith to be Maj.

E. C. Woodhead (late Offr. Cadet, Univ. of Lond. Contgt., Sen. Div., O.T.C.) to be Lt.

Supernumerary for Service with O.T.C.: G. L. Montgomery to be Lt., supern. for serv. with Med. Unit, Glasgow Univ. Contgt., Sen. Div., O.T.C.

The King has conferred the Territorial Decoration upon Lt.-Col. J. K. Lund and Maj. H. J. D. Smythe.

ROYAL AIR FORCE.

C. Crowley, P. J. McNally, and A. E. Vawser are granted short service commissions as Flying Officers.

INDIAN MEDICAL SERVICE.

Lt.-Col. E. B. Munro retires.

Capt. H. Williamson to be Maj.

Lt. C. A. Bozman to be Capt. (prov.).

Temp. Lt. Kailash Nath Tandon to be Temp. Capt.

Temp. Lt. Hasibul Hasan Khan relinquishes his temp. commn.

The King has approved of the appointment of Col. T. G. F. Paterson, I.M.S., to be Honorary Physician to His Majesty, and Col. E. F. Mackie Honorary Surgeon.

Special Articles.

AN INQUIRY INTO ASTHMA.

OBSERVATIONS AT EDINBURGH.

DURING the past eight years a group of workers has been collecting information about asthma in the Edinburgh area. The committee, which consists of Dr. D. M. Lyon, Lieut.-Colonel A. G. McKendrick, I.M.S., Lieut.-Colonel W. F. Harvey, I.M.S., Dr. J. S. Fraser, Dr. R. Cranston Low, Prof. J. Lorrain Smith, and Prof. J. C. Meakins, has sent us the following summary of its findings:—

An analysis has been made of the records obtained from 404 patients suffering from asthma who have been investigated in one of the charges of the Royal Infirmary of Edinburgh during the past eight years. The patients may be regarded as a fair sample of the asthma community, as no special selection was attempted. For the most part they belonged to the hospital class, but a few doctors, students, and nurses were also included. In one respect the sample is open to objection. The proportion of patients under 10 years is less than might be expected, since most young children in this area are dealt with in a special hospital. Between 10 and 50 years the number of asthmatics in each age-group is fairly uniform, but over 50 the numbers rapidly diminish.

Sex.—The series included 215 males (53·2 per cent.) and 189 females (46·8 per cent.), a smaller preponderance of males than is usually described. Between the years 10 and 20 there was some excess of males over females (61 : 31), from 25 to 30 there were 28 females to 14 males, and from the age of 45 to 50 males were again in excess (25 : 12). In other age-periods the proportion of the sexes was about equal.

Age of First Appearance of Asthma.—While the disease may begin at any period of life, our records show that no less than 51 per cent. of the cases began before age 20. At first sight this would suggest that asthma is very largely a disease of youth, but when further adjustments have been considered, it would seem as if the incidence of the disease varies but little at different periods of life.

Heredity.—It was found that some close relative had also suffered from asthma in the case of 38·7 per cent. of the patients examined. Urticaria and similar conditions were not inquired about, as it was thought that the patient's knowledge of these would be too incomplete to afford information of value. Of the 139 cases in whom inheritance was noted, 59·6 per cent. began to have asthma before the age of 20, but when the question is further looked into, it would again seem as if in each age-group the proportion of inheritance cases is about the same, and there is really no preponderance at any one period of life.

Incidents Associated with First Appearance of Asthma.—One of the most striking features of the inquiry has been the very large number of patients (80 per cent.) who were suffering from some respiratory infection just before the asthma started. Other concomitant conditions were rather infrequent in comparison—digestive disorder 7 per cent., nasal condition 12·6 per cent., psychic disturbance 4·6 per cent., skin disease 5·7 per cent.

Occupation.—No less than 75 separate occupations were mentioned by the patients in this series, but few of the groups were of any size. The largest were "household duties" 93, and school 66. Various types of outside work accounted for only 51 cases—a small fraction of the whole. In a certain number of cases, direct evidence was obtained of a relationship between the disease and the patient's occupation. This was particularly noticeable in the case of eight bakers who were sensitive to flour, and three assistants in chemical works sensitive to ipecacuanha and morphia.

Dust.—Exposure to dust was recognised as an aggravating factor by 48 per cent. of the cases. In addition to dust generally, many special kinds were mentioned by individuals. Of these the majority were the common household dusts—floor, carpet, bed, fire, &c., others were associated with various occupations.

Odours and Emanations.—These were less frequently admitted as irritants (20 per cent. of cases). The principal group under this heading was the emanation from various animals or their products (11·5 per cent.). Dusts and odours may act largely as non-specific irritants, but pollens are more usually regarded as specific. Some 13·5 per cent. of the cases got asthma on exposure to pollens, the most common offenders being grass or hay. It is interesting to note that 7·3 per cent. of the subjects suffered from hay-fever in addition to asthma.

Food Substances were complained of by 38 per cent. of the patients, and more than half of these incriminated potato (22·4 per cent.). It may be that the relationship of this article of diet to the occurrence of asthma is an indirect one, by the production of indigestion with a reflex stimulation of the bronchi, since protein skin tests seldom confirmed the patient's objection. Fish, eggs, cheese, and milk were the next largest groups, but each appears only about 10–15 times in the whole series.

Protein Skin Tests were tried out in about 300 patients, and 50 per cent. of these gave positive results. Reaction to one protein only was found in 10·8 per cent. of the cases investigated, the remainder were sensitive to more than one substance. "Multiple" test proteins were employed in a certain number of the subjects, and in these the milk and egg group gave most positives, then in order of frequency came the dandruffs, various meats and certain vegetables. Positive skin reactions were not found more often at any period of life, being distributed fairly evenly throughout the whole series.

Climate.—Asked regarding the relationship of climate to their asthma, 35 per cent. of the subjects replied that their attacks were quite independent of the weather. The others mentioned a large number of different weather conditions as harmful. Cold and damp (65 per cent.) appeared to be the most likely to bring on asthma, but a small number objected to dry or warm weather (18 per cent.). Winds were also complained of, particularly east wind which is often cold and moist in this district. A certain proportion of the patients found that their asthma was definitely seasonal, as, for example, those due to grass pollens. Many believed that their liability to the disease varied with the *season*. As might be expected, most asthmatics were worst in winter, but it was surprising to find that the figure for summer was not far short of the other. Spring and autumn were not often mentioned in this connexion. The value of these observations is probably modified by the fact that the limits of the seasons are not commonly appreciated and summer and winter may merely be employed as indicating good and bad weather. The same arrangement of the seasons was noted in relation to the first onset of asthma, the relative figures for this being winter 101, summer 90, autumn 63, spring 61.

Locality.—Compared with the figures for the general admissions to the hospital, the seaside villages on the shores of the Forth estuary supplied a greater proportion of asthmatics than the inland areas. Not many of the patients examined were able to give satisfactory information regarding the effect of a change of residence, but of those who had noticed its importance 19 per cent. claimed to be worst when at the seaside, 14 per cent. when in the country, and 11 per cent. when in town. A few individuals stated that they were definitely free from all trace of asthma when in certain places.

Psychic Disturbances, such as fright, worry, or emotion induced attacks of asthma in 40·6 per cent. of cases, while fatigue was only occasionally a contributory factor. *Exertion* appeared to be a common cause, but patients did not always clearly differentiate true spasmodic attacks from simple dyspnœa. Of 112 females of active *menstrual* age, 46 per cent. found their asthma worse at or just before the period. A large proportion of the cases claimed that their asthma was likely to trouble them only if they "caught cold," but figures for this are not available, as the relationship was not asked for definitely. On the other hand, *constipation* was not a factor of much importance except in a few instances.

Examination of the *nose*, *throat*, *&c.*, was carried out in 299 cases on first reporting at the hospital. Nasal abnormalities were present in 63·1 per cent. of the asthmatics examined. Enlarged inferior turbinals were found in 40·5 per cent., septal deviations and spurs in 30·7 per cent., polypi in 15·4 per cent., and accessory sinus trouble was noted in 7·2 per cent. of the subjects. The occurrence of skin lesions in this series has already been reported.[1]

Observations not discussed above suggest that many of the patients suffer from minor manifestations of the disease in addition to the typical dyspnœic attacks. One or two of the subjects have described a passing choking sensation of a few minutes' duration on exposure to an irritant, with a fully developed asthmatic spasm during the following night. If a latent interval of this sort is at all common, it might explain the difficulty that exists in so many cases of identifying the irritant.

The analysis of the case records has demonstrated the enormous importance of respiratory infections in the production of asthma in this district. It has shown that the tendency to develop the disease at different periods of life is more uniform than was previously supposed. Many points already known have been confirmed, and percentage figures are available to show the relative importance of various factors. Lastly, the investigation has disclosed many pitfalls, and has suggested precautions which must be observed in order to obtain information of value from such an inquiry.

It is hoped that a more detailed account of the investigation may be published later.

MEDICINE AND THE LAW.

Tenure of Office of Local Government Officials.

LAST week THE LANCET dealt with the decision in Brown *v.* Dagenham U.D.C., establishing the right of the urban council to dismiss at will and without notice its clerk—and inferentially its medical officer of health whose case is governed by the same enactments. Mr. Justice McCardie soon afterwards delivered a reserved judgment in Field *v.* Poplar Corporation, which dealt with the tenure of the office of a chief sanitary inspector in a metropolitan borough. It was a question of the power of the borough council to reduce an officer's salary without his consent. Mr. Field was senior sanitary inspector; he had had various increases of remuneration until 1925, when he was receiving the salary of £450 with the approval of the Minister of Health. In September, 1927, the council desired to effect a general reduction of salaries and notified Mr. Field of the course they were taking. In October they passed a resolution of which the effect was to cut his salary down to a basic figure of £308 plus a bonus varying with the cost-of-living figures, making his total salary for the time being £433 3*s.* 7*d.* He was given no notice of dismissal; he never consented to the reduction, and, though the council took the opinion of the Ministry, the Ministry gave a qualified approval in guarded terms "provided that the council give any notices and obtain any consents which may be legally necessary." Mr. Justice McCardie found great difficulty in unravelling the tangle of enactments governing the situation. He looked at Section 62 of the Metropolis Management Act, 1855, which gave boards of works and vestries the power to appoint officers, to remove them at their pleasure, and to pay them such salaries as they might think fit. Here, so far, the local authority could dismiss officers and alter salaries apparently at will. Then came Sections 1 and 4 of the London Government Act, 1899, which gave the defendant council the powers of a local authority under Section 62 of the 1855 Act. Next came Section 108 of the Public Health (London) Act, 1891, which gave the Local Government Board (now the Ministry of Health) the same powers as they possessed in the case of the district medical officer of a poor-law union in regard to his qualifications, salary, and tenure of office; medical officers of health were to be removable under this section with the consent of the Local Government Board, or by that Board, and not otherwise; and such medical officers were not to be appointed for a limited time only. Sections 106 and 108 of the 1891 Act authorise the Board to make regulations, and one such regulation declared that every sanitary inspector should continue to hold office "for such period as the sanitary authority may, subject to our approval, determine at the time of his appointment," or till he died or resigned, or was removed, or became insane—the last of these contingencies being in the learned judge's opinion by no means impossible if the inspector risked the strain of studying his legal position. "I confess that, if any sanitary inspector spent much time in seeking to unravel the appalling intricacies of Acts and regulations which deal with his duties, status, and rights, he might well develop ere long some obvious symptoms of mental instability." Another regulation enacted that the sanitary authority should pay its officers such salary as the Local Government Board approved. Finally, Section 7 of the Public Health (Officers) Act, 1921, applied Section 108 (2) (*b*) and (*c*) of the 1891 Act to chief or senior sanitary inspectors, thus making these officers removable only by the sanitary authority with the Ministry's consent and not otherwise and making all future appointments unlimited in time. The result of this long sequence of enactments was that Mr. Field could not have his salary reduced unless the Ministry approved; the Ministry had approved in a cautious formula which made Mr. Field's consent a condition precedent. Mr. Field had never consented to the reduction, and therefore the action of the Poplar Corporation was *ultra vires*. There was a possible difficulty in the case, on the point of consent, in that the National Association of Local Government Officers ("Nalgo") might, by its approval of the reduced salaries, have committed Mr. Field to be a consenting party. He had used the services of "Nalgo" in 1920 when they secured a rise in salaries, but the judge held that Mr. Field was not bound by "Nalgo's" acceptance of the reduced scale; Mr. Field had himself voted against the acceptance of the reduction, and the Sanitary Inspectors' Association (of which he was also a member) had protested against it. The language of Mr. Justice McCardie, in summing up the law, deserves the attention of Parliament. "I hope," he said, "the time is not far distant when our local government law will pass from the evils of an almost chaotic obscurity into the region of a lucid and orderly arrangement." When the present proposals for local government reform are passed into law the position will be far more intricate and obscure; it is essential that Parliament should then restate the law in a comprehensive and comprehensible form. At present it has to be extricated from a tangle of statutes and regulations going back for more than half a century and involving references to both local and central authorities long since superseded.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

The Opium Habit.

IT is not only the anti-narcotic zealots who keep a jealous eye on the consumption of opium in India and elsewhere. The question is now being treated as one of practical world import, and the latest evidence of this is that the League of Nations has decided to conduct an inquiry into the use of opium in the Far East. Whether much fresh evidence is likely to come to light is a matter of opinion, but it has to be remembered that numerous investigations have previously taken place, and Lieut.-Colonel R. M. Chopra, of the Calcutta School of Tropical Medicine and Hygiene, has recently conducted a very extensive inquiry into the present position of the opium habit in India. One conclusion at which he arrives is that the opium habit is not nearly so common as might be imagined from some recent publications. There are, he says, areas in every province where the consumption is high, and these areas are being carefully investigated by the local governments concerned, with a view to determining the causes which have led to excessive use of the drug, and possible means of eradicating them. It is stated that the habit is on the whole decreasing, and that the rate of decrease has been much more rapid during the past fifteen years than previously. There are various causes which dispose certain communities to the excessive consumption of opium, and it is noted that one of the most important is the influence of the prevailing religion. Thus, the habit is much more general amongst the Sikhs than in a Mohammedan population, owing to the prohibition of narcotics in the Koran.

The medical profession, which is presumably in the best position to form an unbiased opinion, has usually taken up a moderate attitude on this question, as on the allied one of alcohol. Apart from the purely medical use of opium, in the East at all events, it may be said to have an almost harmless "dietetic," as well as a very pernicious narcotic aspect. In certain agricultural regions it may be said to take the place of a moderate ration of alcohol, and to fulfil a useful stimulant function in the absence of food. In this way it has proved a boon not only to coolies working in the tea gardens and ricefields, but to more enlightened people who have had the self-restraint to use it with discretion. There is also the further consideration that it is so easily obtained, by the cut of a knife on a half ripe poppy capsule, that a rigorous policy of restriction is likely to drive production into underground channels, as has recently occurred in the case of the Bhils of Central India with regard to alcohol; and here as elsewhere it would seem desirable for a policy of education to precede anything approaching total prohibition. While admitting, however, that opium may have reasonable uses, apart from its place in the pharmacopœia, it is well to remember that there is another side of the picture. For its employment in the form of smoking no one can have a word to say, and the custom of administering the drug to infants, for the mere purpose of keeping them quiet, is extremely deleterious. This is one direction in which maternity and child welfare centres are probably having a good effect in localities where they are established. As with alcohol, while admitting that it has its uses, one may question whether the world would not be better off on balance without the juice of the poppy; but in the meantime it would be interesting, as the *Pioneer* observes, to know how far the diminished consumption which is recorded in recent years is being accompanied by the use of cocaine and other preparations far more harmful, which are being smuggled into the country from various parts of the world where they are manufactured.

Euthanasia for the Hindu.

Mr. Gandhi, who at all times has the courage of his convictions, has recently taken a step which is reported to have given rise to great resentment in Ahmedabad, near which city his *ashram* is situated. He has sanctioned the killing of an ailing calf, and in reply to a remonstrance from some of his co-religionists, has expressed the view that to kill an animal which is in great suffering and past all hope of recovery is a religious act. To apply the same principle to humanity, in similar circumstances, is also in his view justifiable. He argues that the idea that mere killing is essentially sinful is erroneous, and that when an animal, or even a man, is in extreme suffering, and there is no prospect of a cure, it is a meritorious action to put an end to life. "I do not feel sorry for what I have done" he says, in reply to censures, "and I think that what applies to a calf must apply to our relatives also." This pronouncement is regarded by most orthodox Hindus as a blow at the very foundations of their religion, and coming from a person with his reputation as a religious leader is a very remarkable sign of the times. One is used to the periodical recurrence of this question of euthanasia in European countries, and also in the United States of America, but to have it brought forward by a Hindu ascetic is something new. Certainly in India the conditions under which hopelessly diseased domestic animals and human derelicts of the lowest classes live must often give rise to thought in this connexion, and even in better surroundings the spectacle of a microcephalic idiot, for example, being artificially fed, in order to preserve a life which would automatically flicker out if left to nature, may well occasion questionings whether in the East or the West. The fact remains, however, that the doctrine of happy dispatch has so far hardly raised its head amongst the Hindus, though suicide is common enough, and it would be curious if a revival of this question, on a practical basis, should have its source in India.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Physical Welfare in the Scottish Universities.

SOME years ago Dr. Tait Mackenzie gave a striking lecture in Edinburgh on his functions as professor of physical education at Pennsylvania University. It was evident that he had developed a system that covered every phase of physical welfare, but which was based primarily on a careful medical examination of the fitness of every student. It was not merely a system of physical education; it was a system for the medical superintendence of growing lads faced with a heavy curriculum. Each student individually had his ration, as it were, of physical exercise carefully prescribed and adapted to his condition. At the lower end of the scale there were men that needed remedial gymnastics; at the upper end of the scale the men were selected for the highest and heaviest games. In a population of some 10,000 students the work of medical professor of physical education was bound to be considerable.

There was a general feeling in Prof. Tait Mackenzie's audience that something of the same systematic kind was required for the Scottish universities. The athletic clubs cover only a small part of the ground and the idea behind the clubs is rather an ideal of competitive excellence in games than of general physical welfare. But matters have since then advanced considerably in the Scottish universities. The University Courts of both Glsagow and Edinburgh have approved of an ordinance increasing the matriculation fee from £2 2*s*. to £2 12*s*. 6*d*. The additional half-guinea is to be set aside as a special fund for the promotion, directly or indirectly, of the physical welfare of students of the University. It is expected that this increase in the fee will take effect as from Oct. 1st next. At the discussion on the ordinance at Glasgow it was clearly indicated that all parts of physical welfare should hang together and, although this additional sum was to be earmarked for physical welfare, the problem of the

Students' Union and related institutions was not being ignored. It is to be hoped that all the Scottish universities will take the proposed view of the health of all the students, both men and women. The curricula in arts, medicine and science are extraordinarily exacting on the physique.

The Milk Problem.

Addressing the students of the West of Scotland Agricultural College, Dr. J. B. Orr, director of the Rowett Research Institute, recently said that if the national importance of milk was appreciated, there would be little difficulty in getting a pure supply. Money spent on an increased use of milk, which would bring the rising generation better health and sounder constitutions, would give a better return to the nation than ten times the same amount of money spent in trying to cure disease. The proper way to deal with the danger of tuberculosis was not to discourage the use of milk but to eliminate the infection. Though this could be done by heating the milk under proper conditions, heating detracted somewhat from its health value, and pasteurised or boiled milk was only a second best. Tuberculosis ought to be eliminated in the cow, and this could only be accomplished by a strong national campaign by the public health authorities.

Some 40 blind women were transferred on Feb. 13th from the Institution at West Craigmillar, Edinburgh, where the accommodation has proved inadequate, to the new home which has been built for them at Alfred-place. The new home, which is believed to be one of the first of its kind and which is to be known as the Thomas Burns Home for Blind Women, is pleasantly situated, and has accommodation for about 80. All the workrooms, dining-rooms, and bedrooms have been constructed and fitted with a view to providing healthy and comfortable surroundings for the women. Wireless listening apparatus is provided next to each bed. The total cost of the building will be between £16,000 and £17,000, of which all but £2500 has already been subscribed.

At a recent meeting of the Glasgow University Court Sir Donald MacAlister, the Principal, commented on the large number of applications from home and overseas which were being received for enrolment in the first year classes in medicine. Of the total received, 79 were from Americans. It was mentioned that normally there was accommodation for 180 students, and the suggestion was made that the limit of enrolment might be fixed at 200.

The late Sir Alexander Ogston expressed the wish that his collection of weapons, arms and curios should be offered on his death to the University of Aberdeen. The collection has been accepted for the Anthropological Museum.

At a meeting of the Society of Antiquaries of Scotland, Prof. Alexander Low related the discovery of a skeleton in a sand pit at Culduthel, Inverness, and Prof. T. H. Bryce reported on two discovered during the excavations at Skara Brae, Orkney, in 1928. Both the Orkney skeletons were those of women, one elderly and one well advanced in middle life, who had suffered severely in life from osteo-arthritis, especially affecting the vertebral column. The leg bones show peculiarities of structure which indicate habitual adoption from early life of the squatting posture.

HOSPITAL CLAIMS FOR ACCIDENT TREATMENT.—At Salop Assizes last week, Mr. Justice Roche tried a claim for damages in a motor accident, in which one of the plaintiffs recovered £1500 and the other £200. Remarking that the man who was awarded the larger sum had received "hundreds and hundreds of pounds' worth of treatment" in the Royal Salop Infirmary, the Judge pointed out that where hospital rules were properly framed expenditure in such cases could be recovered.

Correspondence.

"Audi alteram partem."

ARTHRITIC MUSCULAR ATROPHY.

To the Editor of THE LANCET.

SIR,—In Dr. Beryl Harding's interesting paper on the cause of arthritic muscular atrophy in your number of March 2nd, two forms of atrophy are recognised: one from disuse—e.g., after nerve section—the other from an unexplained reflex. The cause of atrophy which follows upon section of a nerve is obvious, but Dr. Harding points out that the reflex mechanism underlying the atrophy of arthritis is still obscure.

The physiological consequence of an arthritic knee-joint is a flexor reflex affecting the entire extremity. This is due to continuous stimulation of nociceptive endings within the joint, which, in man as well as in animals, tends to evoke reflex withdrawal of the limb. Such a response, owing to reciprocal innervation, is accompanied by *reflex inhibition* of extensor muscles (e.g., quadriceps). One of the striking features of many cases of arthritis of the lower extremities in man is the semi-flexed posture of the knee. This, I take it, is associated with a constant reflex inhibition of the extensor muscles. I believe, therefore, that atrophy of the extensor muscles seen in cases of arthritis is also an atrophy of disuse brought about by reflex inhibition.

If this interpretation holds, it would follow that flexor muscles would show less atrophy than the extensors. I should appreciate it if clinical observers would inform me whether this is in harmony with their experience.

I am, Sir, yours faithfully,

J. F. FULTON.

The Laboratory of Physiology, Oxford, March 2nd, 1929.

To the Editor of THE LANCET.

SIR,—In my presidential address to the Orthopædic Section of the Royal Society of Medicine on Oct. 6th, 1925, I put forward the view that two physiological factors are responsible for the muscular wasting associated with arthritis: "One, a reflex inhibition of the postural or tonic activity of the muscle, about which there is no doubt whatever, and the other, a reflex excitation of the phasic activity of the same muscle, or, in other words, an attempt at reflex protective spasm." The investigations of Dr. Beryl Harding, published in your last issue, appear to confirm this view in so far as she has shown that the muscular atrophy induced by experimental arthritis is associated with an increase of the reflex (phasic) activity of the affected muscles. But the observation that such increased activity occurs in spastic muscles without any diminution in size of the muscles shows that a second factor is necessary to account for atrophy. Lippmann and Selig, quoted by Dr. Harding, have observed that "the atrophy which follows experimental arthritis is preceded by muscular relaxation—muscle collapse—and the subsequent course is the same as that which obtains following tenotomy and nerve section." From this they infer that arthritic atrophy is a disuse atrophy and "is caused by a reflex mechanism." They appear to have missed the significance of the muscular relaxation which precedes arthritic atrophy. It is, of course, the clinical evidence of the reflex inhibition of the postural or tonic activity of the muscle, which I have suggested, is one of the factors responsible for this type of atrophy. As I pointed out in my address, "postural activity alone is able to maintain a state of tension for long periods with hardly any increase of metabolism, as in maintaining ordinary postures. With the help of postural activity a mild phasic activity also can be maintained very economically, as in the condition of

decerebrate rigidity. But without the support of postural action prolonged phasic activity is a most extravagant form of energy and it leads to a rapid using-up of the materials from which the energy is derived." I am, Sir, yours faithfully,

A. S. BLUNDELL BANKART.

London, W., March 4th, 1929.

TUMOURS OF THE SPINAL CORD.

To the Editor of THE LANCET.

SIR,—Dr. J. G. Greenfield asks why I applied "such a meaningless term as 'gliosarcoma'" to a tumour in a report which Dr. Theodore Thompson included in his article on the Diagnosis of Lepto-meningeoma of the Spinal Cord. From the histological evidence, which I attempted to describe, I concluded that the tumour was not a neurinoma, but was composed of neuroglial cells and fibrils—that it "consists of atypical neuroglia." Accepting the atypical nature to be histological evidence of malignancy I proceeded to call the tumour a "gliosarcoma in the less restricted sense of this term"; in its more restricted sense "gliosarcoma" has been applied by some to particular glial tumours of the brain. Surely no term is meaningless when it has been immediately preceded by a definition. I am, Sir, yours faithfully,

HUBERT M. TURNBULL.

Bernhard Baron Institute of Pathology, London Hospital, March 4th, 1929.

THE INJECTION TREATMENT OF VARICOSE VEINS.

To the Editor of THE LANCET.

SIR,—As one who has studied with interest the injection treatment of hæmorrhoids and varicose veins, will you permit me to comment on the letter of Prof. Archibald Young which appeared in your issue of March 2nd? Your correspondent takes up an attitude of Jove-like superiority and rebukes the medical profession of the whole world for adopting methods which have given ample evidence of practical success.

His first argument against the methods is that they are simple, and one gleans the impression that because of their simplicity they are condemned. This simplicity, which, to the ordinary person would appear an advantage, becomes, in the eyes of the critic, a danger. Mr. Young does not state whether, if the method were complicated, he would be more inclined to approve of it, but I feel that the pen of a Samuel Butler would be required to do justice to such a state of mind.

The next objection—namely, that there is no proof that "the method is as effective as operation in cases that really require treatment"—leads one to suppose that Prof. Young cannot yet have seen a completed case. One had begun to hope that the thousands of cases which have been successfully treated in Great Britain and on the continent would have finally laid the bogies of embolism and thrombosis; but they are again raised in this letter without a shred of evidence being called in their support. If the injections are properly given—that is to say, if the solution is introduced into the blood stream and not into the wall of, or outside, the vein—there is no possibility of sloughing arising; and therefore it seems that the cases which Prof. Young has seen have been badly treated. By his remark that he has no inclination to take part in any correspondence that may emerge he puts himself in the position of the small boy who rings the front door bell and then runs down the street; but as much for the sake of neurologists as for the practitioners of injection methods he ought to explain by what process of cerebration he is able to look at a vein for the first time after it has been successfully treated, and say that that vein was never in a condition to be treated. His words are: "... the injection treatment had been carried out upon veins that called for no such active procedure at all." Unless a model of the leg was made before the first injection was given and a detailed note of the patient's symptoms was taken, his claim to reconstitute the size, anatomy, and symptoms of a thrombosed vein endows him with a power of revisualisation which, if extensible, will strike fear into the hearts of others besides the humble practitioners of a simple art.

Finally, no man, however pontifical his mental outlook, should condemn a treatment without advancing arguments. Your correspondent in question vents at length his disapproval of the injection of varicose veins, but disapproval is not scientific argument. One expected that the chief thunderbolt of his wrath would be hurled at the treatment of hæmorrhoids by injection—but the thunderbolt turns out to be only a poor squib, for, just as one cannot multiply nothing, so the threat of "arguments perhaps even more potent" is not likely to frighten those who honestly believe that they are practising a successful, if comparatively unimportant, branch of the healing art. I am, Sir, yours faithfully,

CHRISTOPHER HOWARD.

Sloane-street, S.W., March 1st, 1929.

To the Editor of THE LANCET.

SIR,—Prof. Young says that he "profoundly disbelieves" in the injection treatment of varicose veins, and will not admit that the method is as effective as "operation" (by which I presume he means excision) "in cases that really require treatment." Since May, 1925, I have been continually practising the injection method and have been amazed at the very large proportion of cases that have come to be cured after having undergone the operation of excision once, twice, and even three times; this, however, only confirms the popular feeling that excision is frequently not a permanent cure. I wonder whether the following letter from a patient would be considered proof that the results of injection can be better than those of "operation." It was written in 1926:—

"During my army service I found long marches or standing caused me acute discomfort and it became evident my slightly varicose veins were becoming worse. After standing for some time the thighs felt full as if the skin had become several sizes too small and at night the veins would throb and bubble (like hot-water pipes) so that the relaxed muscles would shake like a jelly—making sleep impossible.

"In October, 1917, both thighs and calves were operated upon. I was four hours on the operating table and had a very uncomfortable ten days till the stitches were removed. Was in hospital seven weeks and it was a further three months before I was fit again. Within eight months the veins began to trouble me again, and in 12 months were worse than before the operation. After demobilisation by wearing elastic stockings and leading a sedentary life I could carry on, but sports were out of the question, as standing for five minutes brought on the "over full" feeling in spite of elastic supports.

"And now to the present time—within a few days of the injections into the thigh veins the 'full feeling' became a mere memory, and now my cure is nearly complete I am looking forward to taking up various sports I had to forego. Even during the treatment I have tested my legs severely on several occasions, including a long day at the motor show (a thing ridiculous to contemplate before even with elastics) without any discomfort whatever. Believe me it is very enjoyable to be out of the semi-invalid class once more. From all points on which I can speak there is no comparison at all between the operation treatment and yours as the injections cause only slight pain, slight discomfort for a short period, and give immediate results.

"I am so enthusiastic about the treatment that I am bringing it to the notice of everybody I can as I feel it cannot be too widely known."

Prof. Young seems to think that a large number of cases of varicose veins do not require treatment, and certainly one would refrain from suggesting to them that they should undergo excision with all its attendant dangers, discomfort, expense, and loss of time in hospital or nursing home. But when a patient seeks

advice, it is because he wants relief from all the pain, weariness, and discomfort he experiences—and these symptoms are often out of all proportion to the actual size of the varicosities—and this relief can be safely and expeditiously given without loss of time or interference with his business engagements, which alone is an economic factor of the greatest importance. I fail to see why Prof. Young should be so contemptuous of the facility with which this method can deal with very minor cases amongst "quite young girls" who are naturally anxious to be relieved of the disfigurement and more especially of the great possibility of gradual increase and extension of the varicosity complained of. I say they cannot be treated too soon.

I am sure that the drawbacks of the method can be eliminated by careful attention to all points of the technique involved. The fact remains that this method of treatment has been hailed by the public, as well as a very large proportion of the medical profession, as a very great boon and justifies itself by the speedy and complete cures obtained, and by great appreciation and gratitude evinced by those who have availed themselves of it.

I am, Sir, yours faithfully,

SIDNEY ALEXANDER.

Welbeck-street, W., March 4th, 1929.

OPERATING FOR APPENDICITIS

To the Editor of THE LANCET.

SIR,—In his Hunterian lecture Mr. Love raises again the question of immediate operation *versus* "delayed treatment" in cases of appendicitis in which the infection is limited to the right iliac fossa, and in support of his decision in favour of "delayed treatment" he cites statistics of cases at the London Hospital over a number of years. Now statistics are notoriously fallacious, and an obvious criticism of these is that no mention is made in them of the number of late cases in which the appendicitis was definitely settling down at the time when they were first seen. I do not think that any surgeon would recommend immediate operation in a case in which the temperature and pulse had fallen to normal and the mass in the iliac fossa was known to be subsiding, and if such cases were included in the group treated by the expectant method, naturally the proportion of successes by this method would be disproportionately raised.

It is in the treatment of those cases seen about the fourth or fifth day in which signs of active, though localised, peritonitis are present that I wish to join issue with Mr. Love. If I understand him correctly, he lays it down as a rule that these cases should be treated expectantly on the ground that operation at this stage is apt to spread the infection. I do not believe this risk is more than infinitesimal if the operation is properly carried out and the following rules are strictly observed:—

(*a*) The peritoneal cavity must be carefully and completely packed off with gauze before the infected area is touched.

(*b*) At no period of the operation must any portion of the gut be allowed to project above the level of the wound during the search for and removal of the appendix, and for this reason no attempt should be made to embed the stump of the appendix.

(*c*) The search for the appendix should be discontinued if it is not easily found, and if the appendix cannot be separated from its surroundings without greatly disturbing their relations, it should be left in situ.

(*d*) Drainage should be confined to the infected area. Why drain the pelvis for an infection limited to the iliac fossa? The insertion of a drain into the pouch of Douglas in such a case can only tend to soil a fresh field of peritoneum.

I cannot help feeling that if Mr. Love's advice is extensively followed and these doubtful cases are left to delayed treatment as a general rule we shall see a rise in the incidence of general peritonitis and of sequelæ, such as subdiaphragmatic abscess, which are now, happily, almost extinct. The lowering of the mortality from appendicitis will be more likely to be brought about by the observance of a more perfect technique in the approach to the inflamed appendix than by allowing Nature, in her leisurely and uncertain way, to dispose of inflammatory products which are a menace so long as they have no safe channel of escape.

I am, Sir, yours faithfully,

R. DAVIES-COLLEY.

Devonshire-place, W., Feb. 26th, 1929.

To the Editor of THE LANCET.

SIR,—There are three points in Mr. Love's lecture which seem to me to call for comment:—

1. The leucocyte count.—Mr. Love finds that "there is no marked rise in the total number of leucocytes until after the fifth day." My experience has been that a leucocytosis of 12,000 to 15,000 is commonly found as early as the second or third day.

2. The treatment of "those cases in which inflammation is limited to the right iliac fossa, and which present themselves from the second day of the disease onwards, as a localised peritonitis or a circumscribed abscess."—Mr. Love points out the high operative mortality in these cases and rightly condemns the routine removal of the appendix when operating on the abscess. This high death-rate is chiefly due, not to the opening of the abscess, but to the removal at all costs of the, often adherent, appendix.

3. The criticisms of delayed treatment.—Non-operative treatment (admittedly advisable under certain special conditions) is, as stated by the late John B. Murphy, "not so much a matter of choice, but a matter of necessity." Mr. Love's criticisms omit the special disadvantage of delayed treatment which lies in the fact that it provides no means of confirming or disproving the diagnosis of appendicitis.

No one is infallible, and since the introduction of delayed, non-operative, treatment, there must have occurred a number of cases in which an incipient peritonitis, due to the escaping contents of a perforated viscus, other than the appendix, has been diagnosed as appendicitis and treated by delayed treatment with results which have been disastrous.

I am, Sir, yours faithfully,

C. HAMILTON WHITEFORD.

Plymouth, Feb. 24th, 1929.

THE SEBORRHŒIC STATE.

To the Editor of THE LANCET.

SIR,—In the annotation which you kindly devoted on Feb. 23rd (p. 404) to my first Lettsomian lecture, there are one or two points on which my views are not quite correctly presented. I did not intend to infer that "relatively little work has been done on the bacteriology of the epidermis"; on the contrary, an enormous amount has been done during the last 25 years, and our knowledge of the subject is fairly complete. The cholesterol fats to which I referred are the chief constituents of the *sebaceous*, not the sweat glands—the amount of fat secreted by the latter is very small. With regard to the "astonishing number of adjuvant organisms" in the common infective lesions of the skin, my own experience is that these lesions are, as a rule, remarkably pure, although the number of actively growing organisms of the given species, even in a trivial lesion, is enormous. Thus the acne comedo and pustule are pure acne bacillus infections, and from most staphylococcal lesions some strain of staphylococcus is usually to be obtained in pure culture. I need hardly call attention to the obvious misprint, scabrous for *glabrous*, in the second paragraph.

I am, Sir, yours faithfully,

H. W. BARBER.

Devonshire-place, W., Feb. 25th, 1929.

THE PREVENTION OF INFLUENZA.

To the Editor of THE LANCET.

SIR,—Last week you gave a useful résumé of how best to avoid and deal with attacks of this infectious disease now prevalent. One pitfall which might have been mentioned has lately been fully discussed by Dr. Lachlan Grant—namely, the danger of washing in "stationary" water in the ordinary wash-hand and lavatory basins. As these basins are used by everybody, healthy or unhealthy, and cannot be sterilised after use, they are bound to harbour infective micro-organisms and thus favour a spread of infectious diseases. Dr. Grant's remedy is to fit all such basins with a raised tap, having a rose wave or jet outlet, removed some distance from the sides of the basin so as to prevent the hands coming into contact with its contaminated walls. By this device ablutions are performed in pure fresh water, all infective particles being conveyed direct to the soil pipe. I am, Sir, yours faithfully,

RITA C. WEIR, M.B. Glasg.

Bacteriological Laboratory, Ballachulish, Argyleshire, March 3rd, 1929.

AGRANULOCYTIC ANGINA.

To the Editor of THE LANCET.

SIR,—Dr. Batten's report of a case in your last issue (p. 440) draws attention to a condition which, if not actually so infrequent as some think, is at least very seldom diagnosed. He suggests that further work should be done with regard to arriving at the ætiology of the condition and to finding some method of treating it.

In Germany some good results have been obtained by the application of X rays (in mild doses) to the long bones with a view to stimulating the output of leucocytes. A few cases were treated thus with success in Berlin in the summer of 1927. I saw two cases of agranulocytic angina treated in this way by Eppinger, of Freiburg; one was a nurse, but she was almost moribund before the treatment was tried and died shortly afterwards; the other, a woman of 42, made quite a remarkable recovery, although her white count was very low before the institution of the treatment (800 per c.mm.) Eppinger showed this case later at a meeting of the Freiburg Medizinische Gesellschaft. I am, Sir, yours faithfully,

Cricklewood, March 5th, 1929. P. J. MOLLOY.

THOUGHTFUL GRATITUDE.

To the Editor of THE LANCET.

SIR,—When a medical man who is in ill-health asks for the advice of a consultant and obtains it without any fee, how well it would be if it were an understood rule that he should send a cheque, according to his circumstances, to one of the medical charities, such as the Royal Medical Benevolent Fund or the British Medical Benevolent Society. A little more thoughtful gratitude on the part of the profession would vastly increase the well-known usefulness of those institutions.

I am, Sir, yours faithfully,

JAMES G. MACASKIE, L.R.C.P. & S. Edin.

Princes-square, W., March 4th, 1929.

*** The hon. treasurer of the Royal Medical Benevolent Fund is making a special appeal for financial help to the Fund at this time of year when poverty is made the harder to bear owing to illness and bodily suffering. Subscriptions are urgently needed to enable the committee to meet many calls which are made by members of our own profession, their widows and dependents, who are afflicted by poverty and want. Some have no friend or relation to whom they can turn and are dependent on this Fund alone. A number of cases which were relieved at the last meeting are described on p. 534. Subscriptions and donations may be sent to him at 11, Chandos-street, London, W.1.—ED. L.

Public Health Services.

INFLUENZA.

CLINICAL reports indicate that the epidemic is still very widespread, although in most places remaining mild in form. Numerous cases of pneumonia are occurring in Leeds, but there is some doubt whether the majority of these are secondary to influenza or primary. Sheffield reports a widespread but mild epidemic of influenza, and in Leicester town and county a severe type of the disease is reported and a rather severe type also in Northamptonshire. Reports from Birmingham and North Staffordshire suggest that the disease is on the increase and the epidemic does not appear yet to have reached its peak in the Midlands generally. The disease is still very prevalent in Manchester and other Lancashire towns, as well as in Newcastle-on-Tyne and the North, but in Liverpool it is decreasing rapidly. The Eastern counties are also affected. A mild form of the disease is reported from South Wales, while North Wales and Gloucester are stated to be free. In Scotland, during the week ended March 2nd, the aggregate death-rate for the 16 towns was 19·1, that for Aberdeen being 30·2, Glasgow 17·8, Edinburgh 21·4, and Dundee 19·9. Deaths from influenza and respiratory diseases numbered 67 and 213 respectively and 298 cases of pneumonia were notified.

On the Continent a marked increase in the number of deaths occurred in the Rhine districts as far south as Mannheim, which had so far been unaffected by the epidemic. Thus the death-rate of Mannheim rose in a single week from 11·5 to 23·2 per 1000 inhabitants, that of Dortmund from 14·2 to 21·0. In the Netherlands the epidemic is causing some difficulty in the public services. The town most severely affected is Arnhem, near the German frontier, where the death-rate rose to 43·9 per 1000 during the week ended Feb. 22nd. In Paris during the first ten days of February influenza deaths were numerous, the general death-rate rising to 28·7; there was a similar increase at Lille, and the epidemic extended as far south as Lyons, where a death-rate of 32·6 was registered during the week ended Feb. 20th. The Italian Health Service reports a spread of influenza, particularly in the provinces of Northern and Central Italy. The prevailing type remains mild and complications are rare. An increased mortality has been observed as far east as Budapest, but Warsaw has as yet not been affected. The epidemic is generally abating in the Scandinavian countries. In Spain the reports of Feb. 18th show an all-round decrease. Switzerland has had the disease only in mild form; up to Feb. 9th the general mortality was very low for the season of the year. In parts of Czecho-Slovakia influenza is increasing. The epidemic in the United States of America is now virtually at an end.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED FEB. 23RD, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 275; scarlet fever, 2150; diphtheria, 1098; enteric fever, 30; pneumonia, 4451 (last week 3658); puerperal fever, 43; puerperal pyrexia, 150; cerebro-spinal fever, 16; acute poliomyelitis, 4; encephalitis lethargica, 21; dysentery, 9; ophthalmia neonatorum, 83. No case of cholera, plague, or typhus fever was notified during the week.

Notifications of pneumonia have again risen considerably after a drop last week, the figures for the last six weeks being 1936, 1864, 2422, 3511, 3898, and 3658 respectively. Counties reporting a large number of cases of pneumonia are as follows: London 554 (last week 562); Chester, 155 (173); Derby, 53 (64); Devon, 47 (38); Durham, 244 (168); Essex, 128 (167); Kent, 92 (74); Lancaster, 783 (906); Leicester, 52 (42); Middlesex, 189 (150); Northumberland, 167 (100); Stafford, 209 (113); Surrey, 78 (69); Warwick,

313 (131); Yorks West Riding, 597 (296); from which it will be seen that the north is largely responsible for the increase.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Feb. 26th–27th, was as follows: Small-pox (46 under treatment, 1 under observation); scarlet fever, 1745; diphtheria, 1996; enteric fever, 10; measles, 64; whooping-cough, 1005; puerperal fever, 17 (plus 7 babies); encephalitis lethargica, 80; poliomyelitis, 7; "other diseases," 65. At St. Margaret's Hospital there were 8 babies (plus 3 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 4 (0) from enteric fever, 88 (1) from measles, 12 (4) from scarlet fever, 249 (80) from whooping-cough, 54 (6) from diphtheria, 66 (13) from diarrhœa and enteritis under two years, and 1764 (473) from influenza. The figures in parentheses are those for London itself.

The number of deaths from influenza during the previous eight weeks was 83, 99, 122, 179, 321, 652, 987, and 1243 respectively, the figures for London during the same period being 15, 18, 34, 39, 77, 198, 331, and 393, from which it is seen that the rise has again become somewhat steeper. In the week under review deaths were attributed to influenza: Leeds, 136; Manchester, 95; Birmingham, 80; Oldham, 57; Bolton, 52; Hull, 46; Leicester, 38; Stoke-on-Trent, 37; Stafford, 34; Liverpool, 33; West Ham, 29; Croydon, 28; Norwich, 26; Reading, 21; and 26 other great towns with 10 or more. (Glasgow reported only 28, Edinburgh 27, Dublin 34, and Belfast 20.) The figures for the week ended Feb. 23rd, to complete the Registrar-General's comparative table of influenza death-rates (printed last week), are as follows: aggregate, 4·67; North, 5·19; Midlands, 3·84; South, 3·52; Wales, 1·20; Greater London, 5·35. Birmingham reported 13 deaths from measles, Liverpool 12, Sunderland 9, St. Helens and Cardiff 7 each, and Gateshead 6. The deaths from whooping-cough are widely distributed, the highest figures coming from Manchester, 23; Bolton, 14; West Ham and Oldham, 9 each. Liverpool reported 10 deaths from diarrhœa, Salford 6, Manchester 5.

The statement of deaths from small-pox for the month of January for areas outside the county boroughs and great towns included 4 deaths assigned to Durham, Jarrow (M.B.), Lancaster, Mossley (M.B.), Monmouth, Tredegar (U.D.), Flint, St. Asaph (R.D.).

The number of stillbirths registered during the week was 326, corresponding to a rate of 46 per 1000 births, including 67 in London.

Deaths in London during the Recent Severe Weather.

The Registrar-General also gives an instructive table showing the great increase in the number of

Week ended—	Influenza.		Respiratory diseases.		Heart and circulatory diseases.	
	All Ages.	Age 65 years and upwards.	All Ages.	Age 65 years and upwards.	All Ages.	Age 65 years and upwards.

deaths, especially among old people, from influenza and from respiratory and circulatory diseases, in London during the recent severe weather. He remarks that the statement may probably be regarded as indicative of similar increase in the country generally.

RADIUM AT BRADFORD.—The annual report of Bradford Royal Infirmary states that a radium therapy department is being created, and it is expected that it will be in working order a few weeks hence. An appeal for £20,000 to equip the clinic and provide an adequate supply of radium has, so far, produced a little over £5,000. The average cost of each occupied bed was about £143. A Charter of Incorporation is to be applied for.

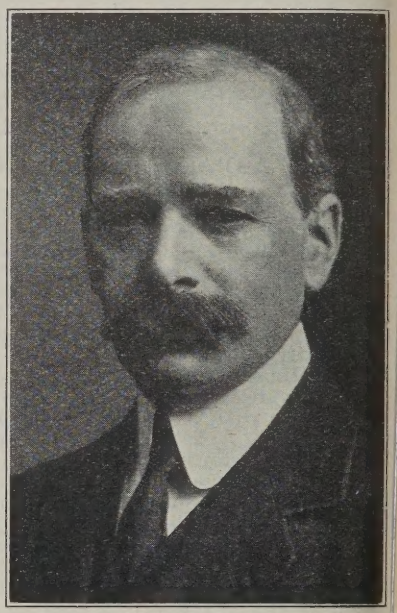
Obituary.

SIR HECTOR MACKENZIE, M.D. CAMB., F.R.C.P. LOND.,

CONSULTING PHYSICIAN, ST. THOMAS'S AND BROMPTON HOSPITALS.

WE much regret to announce the death of Sir Hector Mackenzie, which occurred at his residence in Upper Brook-street after a short illness on March 2nd in the seventy-third year of his age.

Hector William Gavin Mackenzie was born in Edinburgh in 1856, the son of Mr. J. Urquhart Mackenzie of that city. He was educated at the University of Edinburgh, where he graduated with honours, and Emmanuel College, Cambridge, where he was a foundation scholar. In 1880 he was Fifth Wrangler in the mathematical tripos, and was duly elected Fellow of his college. By this time he had decided to become a medical man, and joining the school of St. Thomas's Hospital he obtained the diploma of M.R.C.S., and graduated in medicine at Cambridge in 1884, when he also took the diploma of M.R.C.P. He proceeded to the M.D. in 1888, and having held the usual minor posts in the hospital was elected resident physician and medical registrar. He was at the same time assistant physician and pathologist to the Royal Free Hospital, and was also elected assistant physician to the Brompton Hospital, where he acted as pathologist. All of these posts by a quiet but unrelaxing attention to their various claims he managed to fill with remarkable competency, amassing an immense and varied store of clinical experience which he kept always at his immediate disposal. In 1892 he was elected F.R.C.P. having now become assistant physician to St. Thomas's Hospital, where he was lecturing on pharmacology and therapeutics. In 1900 he became full physician to the hospital, and until the time of age retirement discharged his duties towards patients and students alike in an admirable way.



SIR HECTOR MACKENZIE.

Photograph by Lafayette.

Mackenzie's connexion with the Royal College of Physicians was an important one. He was censor from 1916 to 1918 and senior censor in 1921 and 1922. In 1916 he delivered the Bradshaw lecture, taking as his subject Exophthalmic Goitre, and in 1922 the Lumleian lectures upon the Diseases of the Thyroid Gland. These two subjects he made particularly his own, while in delivering the Bradshaw lecture he was able to show that he had for many years been interested in exophthalmic goitre, for in dealing with the incidence of the disease he brought forward the records of 438 cases, of which 263 were seen at St. Thomas's Hospital and 175 were private cases, no doubtful or incomplete cases being included in the

series. A summary of results and views on operative treatment was succinctly given, and the conclusions were come to that ligature of the thyroid arteries should only be a forerunner of thyroidectomy, which itself does not cure unless a sufficient amount of gland is removed. It is interesting to note that these conclusions were reached some years after in the articles on diseases of the thyroid which he contributed to Allbutt and Rolleston's "System of Medicine." The contribution to that System on the subject of exophthalmic goitre is a comprehensive and interesting essay in which the dangers and advantages of surgical methods of treatment are summed up in a critical way. The author's personal share in the discovery of the value of the internal use of thyroid preparation is, characteristically, well-nigh concealed.

In respect of further writings Mackenzie's long and assiduous work at the Brompton Hospital was reflected in an essay on physical signs of the lungs and heart also contributed to Allbutt and Rolleston's "System of Medicine." The difficult task of expressing in writing descriptions of sounds as they are to be heard in certain places or in certain circumstances was here most anxiously undertaken and in a very successful manner.

Hector Mackenzie was a learned doctor and a successful clinician, and his death will be deplored by a large circle of friends and patients.

CHARLES MAXWELL EKINS, M.R.C.S. Eng.

Dr. C. M. Ekins, whose death occurred at the Anglo-Swiss Hospital at Alexandria on Feb. 10th, was the eldest son of the late Major-General Charles Chester Ekins, Indian Army. He studied medicine at University College Hospital, and in his student days was a prominent Rugby football player. He went to Egypt at the end of the South African War, in which he had served as civil surgeon, and entered the Department of Public Health of the Egyptian Government Service. After a few years' experience in the provinces, he was appointed in 1906 to the important post of director of the government hospital at Alexandria. This post he held until 1924, when in conjunction with many other British officials he retired from the government service. "During these 18 years," writes a colleague, "he did not spare himself in his endeavour to make the hospital efficient and to keep it so. At this time he won very general affection and esteem. As an administrator he was fair and just. But he was much more than an administrator and organiser; he remained always the clinician. On retirement in 1924 he started private practice. This he greatly enjoyed. The humanity of the man, his bright and cheery manner, his sympathy with sorrow, his knowledge of people, together with his wide medical outlook, made him beloved and a success wherever he passed. He will be missed by a wide circle of patients and friends."

A year ago Dr. Ekins became honorary physician to the Anglo-Swiss Hospital, Alexandria, and six months later was appointed its honorary medical director. Unfortunately his health broke down during the summer, when on vacation in England, and this illness necessitated an operation from which he never properly recovered.

Dr. Ekins married Sara, daughter of Mr. Edward Pentilli, late of Alexandria, and she survives him.

ALEX HILL, O.B.E., M.D. Camb., F.R.C.S. Eng.

Many of our readers will have seen last week with much regret the announcement of the death of Mr. Alex Hill, neurologist, scholar, and a well-known authority on education, which occurred on Feb. 27th at Upper Bassett, Southampton, at the age of 73. Alex Hill was the son of John Hill, of Loughton, Essex, a London stockbroker, and was educated at University College School and Downing College, Cambridge, where he graduated with distinction, and was duly elected a Fellow in 1880. Deciding to enter the medical profession—Downing having always had distinct affiliations with medical science—he joined the medical school at St. Bartholomew's Hospital, and qualified by graduating in medicine at Cambridge and taking the F.R.C.S. Eng. For a time he worked at Cambridge and elsewhere in neurological research, delivered Hunterian lectures at the Royal College of Surgeons of England, 1884–85, translated a well-known German book on the central nervous organs, and established a position along this line of work which was later recognised by election as President of the Neurological Society. But in 1888 he was elected Master of Downing College, and from this date forwards his name has been constantly associated with developments in secondary education. He was Master of Downing for some 20 years, being Vice-Chancellor of the University in 1897 and the following two years. During his tenure of office he became widely recognised as an authority on education generally, though his publications on the subject were confined mainly to scientific aspects. Five years after his resignation of the Mastership of Downing he was appointed principal of University College, Southampton, a post which he held for seven years. He became President of the Teachers' Guild of Great Britain; he was a Commissioner in 1901 reporting to the Treasury on Universities and Colleges; he was a member of the Welsh Colleges Committee; secretary to the Congress of Universities of the Empire in 1912; and for 20 years chairman of the National Home Reading Union. Wherever, in short, there was practical work to be done, in association with the multifarious sections into which the conduct of education falls, Dr. Alex Hill was ready with his time, his work, and his enthusiasm. From the strict paths of medicine he had long strayed, but his travel-books show his abiding interest in medical progress.

ALBERT REVERDIN, M.D. Lausanne.

Dr. Albert Reverdin, who died on Jan. 29th at the age of 48, was one of the most renowned and popular medical men in Switzerland. He was the son of one well-known surgeon, Auguste Reverdin, and the pupil of another, having been chief assistant to César Roux, in Lausanne for many years. In 1912, being greatly interested in the work of the Red Cross, Reverdin went to the Balkan war to assume the direction of the "Vaud-Genève" ambulances. He proved to be an efficient organiser as well as a distinguished surgeon, and received honours from Serbia and from Greece. He returned to Geneva in 1913, and began to build a big up-to-date clinic. Then the Great War broke out. Reverdin at once offered his services to the French Government, and was entrusted with the charge of the large War Hospital in Bourg, being appointed also surgeon-in-chief and inspector-general of the VIIth region. For his war services he was made an officer of the Legion of Honour. In 1919 he was able to return to Geneva to open his new clinic, which was equipped with X ray plant as well as fine operating theatres, consulting rooms, and research laboratories. Besides his clinical work, Reverdin for some years held the post of chief of a surgical department at the Hôpital Cantonal de Genève. As a vice-president of the International Red Cross Committee he brought about a great number of useful reforms, and he devoted much of his time to this work. The brancard he invented is now used widely in armies.

Dr. Robert Duby, of Geneva, writes: Those who saw Reverdin operate were struck by his great dexterity and rapidity of action. As an inventor he distinguished himself in many directions. In surgery we have Reverdin's needles, Reverdin's pincers, &c. We owe him also Nidrose, a malleable substance, which in many cases can take the place of plaster. With his technical skill was associated excellent judgment. Severe with himself, he was severe with others, and there was military discipline in his operating-room as well as in the whole clini c

But he was interested in his patients from the moment they entered the clinic, and he never forgot them. To him the operation was an important part in the treatment of their illness, but not the only thing that counted. He avoided operating when he could. Because he was a master of surgery and yet was never mastered by it his name will be remembered as a great clinician, and his early death will be deplored by the increasing circle of practitioners who relied on him for sound advice.

JOHN LAIRD, L.R.C.P. IREL.

THE death occurred at Glenarm, Co. Antrim, last week of Dr. John Laird, who practised in Sligo for some 50 years and retired a few years ago. He was 86 years of age. He obtained the licence of the Royal College of Surgeons in Ireland in 1865, and of the King and Queen's College of Physicians in 1868. Having spent a year or two in hospital work in England, he was elected dispensary medical officer for the Sligo district while still a very young man. He speedily acquired the reputation of a careful and able practitioner, and for half a century he was one of the leading physicians and obstetricians in the West of Ireland. Tuberculosis was and is very common in that region, and he gave special attention to the study of that disease, having a considerable success in treatment. In 1912 he published his views in a small book, "Notes on the Treatment of Tuberculosis," of which a second edition, entitled "Tuberculosis: Its Prevention and Treatment," appeared in 1925. Though the theories he had arrived at are not likely to be accepted, the book is the fruit of wide reading and careful observation. Dr. Laird was a man of retiring disposition who took little part in public affairs, but he was held in high respect for his personal and professional qualities by the public and by his colleagues.

FREDERICK CLAUDE EVILL, M.R.C.S. ENG.

Dr. F. C. Evill, whose death occurred at Worthing on March 3rd, had been in practice in High Barnet all his life. Born at New Wandsworth in 1861, he was educated at Clifton College and St. Bartholomew's Hospital, London, qualifying in 1886. He was then house physician at Brompton and house surgeon at Bart.'s and at the Central London Ophthalmic Hospital, before a breakdown in health occasioned a voyage to Australia, where he remained for six years as surgeon to the Broken Hill Hospital, N.S.W. As a practitioner in an important residential suburb he kept closely in touch with scientific medicine, as his occasional but weighty contributions to medical literature clearly testify, and he was for thirty years surgeon to the Victoria Cottage Hospital at Barnet. As a young man Dr. Evill was an unusually accomplished amateur actor, and those who may have seen him in hospital entertainments, notably at Bart.'s and Brompton, will long remember the compelling humour of his characterisations. He was also in his early days quite a good amateur painter.

LEEDS AND BOLTON WORKERS' PENNIES FOR HOSPITALS.—The Leeds Workpeoples' Hospital Fund has had a record year. The sum collected in 1928 was £44,560, an increase of over £1000 compared with 1927. Almost the whole of this sum has been collected in the workshops, factories and clubs in the city, chiefly by means of weekly collections of coppers. The fund maintains two convalescent homes in Yorkshire, and last year 614 women and 676 men enjoyed rest and recuperation in them. Grants totalling £33,427 were voted at the forty-second annual meeting. These included £23,077 to the Leeds Infirmary, £3551 to the Leeds Dispensary, £2959 to the Leeds Women's and Children's Hospital, and £947 to the Leeds District Nursing Association. Since its inception the fund has distributed over £1,000,000. The workpeople of Bolton and district by giving 1*d.* or 2*d.* from their wages each week, contributed last year £16,400 in aid of the funds of the infirmary.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

MEDICAL MEN AND THE ARMY.

IN the House of Commons on Thursday, Feb. 28th, Sir L. WORTHINGTON-EVANS (Secretary of State for War) introduced the Army Estimates for 1929, and said that the House might not perhaps appreciate the extent to which men of eminence in their respective professions were willing and anxious to place their experienced advice and expert knowledge at the disposal of the Army Council. He would like to draw special attention to the assistance which was given to them by members of the medical profession. The Army could derive nothing but benefit from a good understanding between the civilian and the military branches of the medical profession, which he was happy to believe was the aim of both and which displayed itself in their fruitful coöperation on many committees. He hoped that as the scope and attractiveness of the Army Medical Service became better known through their advocacy the present welcome increase in the number of candidates might continue. They were, however, still suffering from a serious shortage of candidates for commissions in the regular army. The shortage was, he believed, mainly due to economic reasons. He believed that the Army offered just as good a career as ever it did.

In the debate which followed,

Mr. BECKETT raised the question of the circumstances under which men are invalided out of the army. He had had cases brought to his notice where men who were beginning to make their way upwards had been discharged on medical grounds without adequate reason. A lot of kind things were said about army doctors; he dare say they were true. His own experience was at an abnormal time of rush and he may have been prejudiced. But, however adequate the average army doctor might be as a general practitioner, he was not an ultimate authority when it came to the question of a serious and deep-rooted disease. These men who were discharged had no appeal. The Admiralty had given way on this point and had agreed that men discharged on medical grounds should have the right of independent appeal. Was it not fair that the Army should give a similar concession?

Replying to the debate, Mr. DUFF-COOPER (Financial Secretary to the War Office) assured the House that there was an improvement in the health of our troops in China.

HOUSE OF LORDS.

TUESDAY, FEB. 26TH.

LOCAL GOVERNMENT BILL.

The LORD CHANCELLOR, in moving the second reading of the Local Government Bill, said that local government in this country was firmly rooted in our traditions and formed part of the essential framework of our democracy. Since the limits of local government must be defined by statute and could not have the flexibility of common law, it followed that as the conditions changed difficulties must arise which the old traditions were unable to meet, and development must be hampered by restrictions which by the effluxion of time had become obsolete. The present system was laid down in 1888 and had not been substantially altered since 1894, and when they recollected the changes which had taken place in our civilisation, in the means of transport and even in the conception of the duties of citizenship since that date, it was not surprising that the time had now come when a change was almost essential if the efficiency if the machinery was to be maintained.

The first problem with which this Bill occupied itself was one which had long been recognised as urgently requiring consideration—namely, the problem of the poor-law. The present system dated back to 1834, when the present poor-law unions were established. Boards of guardians were set up charged with the responsibility of relieving poverty within their areas, with powers of raising money which no local council could interfere with or control, in areas which had remained fixed ever since, although the whole industrial revolution of this country with all the changes of distribution of wealth and population which that revolution had brought about had taken place after the date when those boundaries were first allotted. The boundaries in many cases cut across local government areas and embraced in one union parts of different parishes or even counties. The poor rate varied to-day in different unions from 2½*d.* in the £ to 10*s.* 6*d.* in the £, and in the same county they could find one union which levied a poor rate of 7*s.* in the £ and another which levied one less than 1*s.* in the £. It was no reflection on the capacity

of the men and women who had given many years of invaluable service to a very laborious public work to say that the present system of boards of guardians was obsolete in its construction and unjust in its operation. Its abolition had been advocated by every party in the State. That point was one on which both the Reports of the Royal Commission of 1909 were agreed and it was the subject of a unanimous recommendation from the Maclean Committee some nine years later. Rates were originally levied mainly for the relief of the poor and the payment of certain minor country expenses. When during the middle of the last century public interest began to awaken to the importance of public health and to demand from the rates the provision of adequate social services in the way of drainage, water-supply, and so on, England's industrial supremacy was still at that date unchallenged. Any burden which a local factory was called upon to bear could be passed on without undue difficulty to the consumer in markets in which he held the practical monopoly. All that was changed to-day when we found ourselves in every foreign market competing bitterly with those who were once our customers and who were now our rivals. To-day the burden of taxation might make all the difference between the survival and the extinction of an industry. Of all taxation rates were perhaps the most burdensome. Now that the rates were the recognised means of providing so many social services which in old days were entirely outside their scope, it was not right that industry should be called upon to bear the full burden of their provision without regard to the question whether there were funds available out of which to make such provision. Proceeding to deal with the

Relationship between the National Exchequer and the Finances of Local Government Areas,

the Lord Chancellor said that the result of the percentage grant system was that the amount received by the local authority depended not upon its need, but upon its expenditure. The Government had seized this opportunity so to adjust the relations as to secure that the Exchequer grant should go where it was most needed and that the provision of money from the national Exchequer should be regulated in such a way as still further to redress the inequalities which the spreading of the areas would not completely extinguish. Three matters had been taken into account—the poverty of the district, abnormal unemployment in the district, and the sparseness of population in the district. In order to make allowance for the poverty of the district an addition was made to the actual numbers of the population by taking into account two matters: (1) the rateable value; (2) the number of children under 5 years of age. This latter factor was brought in because it had been found in practice that the poorer districts were those in which the larger number of children were to be found. While the formula was admittedly complicated in statement as an arithmetical formula, he claimed that in operation it was quite simple. By its aid it was believed that a means had been evolved which without any claims to mathematical accuracy so adjusted the grant of public money from the National Exchequer to the various local areas as to ensure that each received according to its needs and that the inequalities of the past would disappear for the future. Machinery was provided in the Bill for the easy readjustment of local boundaries both between districts and electoral areas. Commenting on the provisions of Part I. of the Bill, the Lord Chancellor said that one of the great advantages of this part of the Government scheme was that the overlapping which had existed in the past ought in the future to cease, and that it would be possible by centralisation and specialisation in selected institutions to provide a far more highly skilled service than was possible to-day. There was given power for different poor-law authorities to combine for the provision of an institution which neither singly might be able to afford, but which might be essential in isolated cases. The Bill provided that the existing disqualification of guardians who had received poor-law relief should be extended to the new authorities, but that the disqualification should not exist by reason only of the receipt of medical or surgical relief in an institution. Express power was given to the county councils for the provision of hospitals and maternity homes, or for the making of subscriptions or donations to existing hospitals and institutions. Provision was made for the recovery from those who accepted assistance in these public institutions of a contribution towards the expense, but this did not apply to infectious disease hospitals, including those for the treatment of tuberculosis and venereal disease, since it was in the interests of the public at large that persons should be isolated in those institutions as soon as possible. Further provision was made to enable the Minister of Health to postpone the operation of the Bill in those cases in which it had been found necessary to supersede the existing board of guardians by reason of their default. Under Part 3 of the Bill, which embodied amendments of the law with regard to highways, provision was made for the county councils as the highway authorities to be given powers under the Town Planning Act—powers which many people thought they ought to have had from the commencement. Provision was made under Part 4 of the Bill for various minor alterations in local government law; for instance, the acceleration of the process under which medical officers of health became full-time servants of the State, and the making of regulations prescribing the qualifications of such officers and of health visitors. Provision was further made for a survey by county councils of the existing accommodation of hospitals for infectious diseases, and the preparation of a scheme where necessary for the provision of adequate accommodation. In conclusion the Lord Chancellor asked their Lordships to say that the Government had correctly diagnosed the ills under which local government was suffering, and that the remedies that they had prescribed were well calculated to cure those ills. Finality in progress or perfection in execution were beyond human achievement. He made no claim for either in this Bill; but he did claim that for many years to come the measure would stand out as a landmark in the progress of local government in this country, and as a monument to the vision and courage, to the breadth of conception, and mastery of detail of the Minister of Health.

Rejection of the Bill Moved.

Lord PARMOOR, in moving the rejection of the Bill, urged that the diagnosis to which the Lord Chancellor had referred was wrong, and that the suggested remedies would not cure the ills that existed. The inequity of our rating system consisted in placing on ratepayers the charge of mainly national services. The Bill did nothing to put an end to that glaring inequity. The poorer districts would be worse off than at present. The excellent work which had been done by poor-law guardians would not be adequately performed in future as the new local bodies were to be given no responsibility either as regarded policy to be followed, the money to be provided, or the officials to be appointed. He contended that the vast majority of students of the poor-law system to whatever party they belonged, felt that the expense of able-bodied unemployed should be a charge on the State and not on a particular locality. He thought that the principle of a block grant was a mistake, and that a far better way was to found the grants on efficiency.

After further debate the discussion on the Lord Chancellor's motion was adjourned.

WEDNESDAY, FEB. 27TH.

The adjourned debate on the second reading of the Local Government Bill was resumed.

Increased Powers of the Ministry of Health.

Earl BEAUCHAMP said that it would be idle for the most determined opponent of the Government to declare that there was not a considerable amount of good in the Bill. But it was the business of the Opposition to concentrate on criticisms, and there was, in the first place, a considerable increase in bureaucratic powers. There was, running all through the Bill, an increase of power to the Minister of Health and to the members of the Ministry. With the two principles underlying the Bill—the necessity for some change in local government and the relief from rates—they all agreed; his criticisms were as to the methods by which it was proposed to apply these principles. In regard to the reform of the poor-law the Government proposals were not bold enough. The problem of the able-bodied unemployed was entirely shirked. Was there not something in the complaint that the county councils would be having too much work placed upon them and that their duties would be increasing to such an extent that it might become difficult in the future to find people to undertake them? The Bill did not break up the poor-law, but transferred the work to other bodies. Poor-law functions, he suggested, ought to be split up in three directions—the oversight of mental deficiency in children should be given to county and borough councils; relief of the able-bodied poor should be delegated to the insurance committees of which they had heard something, and linked up with unemployment insurance; and the relief of the other poor should be dealt with by Home Assistance Committees. Referring to the maintenance of health services, Lord Beauchamp said he distrusted the system of block grants. Percentage grants had not done badly on the whole, and he suggested that there might be a combined system beginning with block grants, followed by percentage grants, so as to encourage local authorities to spend more on health services than they were spending now.

A Constructive Measure.

Lord DAWSON said that whatever opinions might be held on the Bill all would be agreed that it was a great constructive measure which showed vision and far-reaching knowledge. For himself, in spite of the lucid exposition given by the Lord Chancellor, he still found himself in the mazes of derating. He proposed to limit his remarks to Part I. of

the Bill, of which he had some knowledge, and particularly to that part of it which concerned the foundations of hospitals. He did so with less hesitation because in the House of Commons pressure of time was such that discussion was strictly limited. In the clauses of Part I. there were provisions which enabled and, more than that, might easily encourage councils to found general hospitals for the treatment of general medical and surgical disease. Whether this was a right or wrong policy it was a new departure and one which probably ushered in a new era in the administration of medicine in this country. He was inclined to think that the proposals were right if they were suitably safeguarded. He asked the House to imagine the whole field of curative medicine, of which neither the councils nor their medical advisers had had any previous knowledge or experience. They had gained a certain limited knowledge in the application of curative medicine in the tuberculosis clinics and in maternity. As regarded that large field of general surgery and medicine treated in the general hospitals of this country their experience amounted to extremely little. The fact that the councils had run poor-law hospitals was but little training for the running of big general hospitals such as they knew them and understood them. These powers which were given in the Bill would enable the councils not only to convert poor-law hospitals into general hospitals, but give them the power of founding general hospitals. These powers came at a time when the demand for hospital accommodation was increasing throughout this country. The fact was that the hospitals were no longer the need of a class; they were the need of the whole nation. They used to be for the sick poor; now all were poor and sometimes sick. Anyone might need a hospital in these days. The progress in knowledge demanded it. Social and economic conditions demanded it. The first reason was the progress of knowledge.

Team Work Necessary.

The art of medicine, Lord Dawson continued, now called to its aid a number of sciences, sciences mobilised on its behalf. These new sciences required team work. Years ago a cough or a disease of the chest required a stethoscope and a bottle of medicine. To-day they required besides the clinical knowledge of the physician the radiologist and the bacteriologist. A surgeon who wished to operate on the stomach now required besides his own skill the skill perhaps of the chemist or the radiologist. In other words, there was the necessity of bringing together many branches of knowledge which had to act in coördination if they wished to attain their result. That could only be done by organisation. Each of these specialties required its equipment. These equipments had to be brought together not only for efficiency, but for cost, because they had this striking fact that the more science progressed the greater the cost of treatment became. Therefore, but for what he might call mass production, a large proportion of the community would be without those benefits. That, then, was a reason why people in increasing numbers needed institutional treatment, which in other words was hospital treatment. It was a fact which had to be admitted that the voluntary hospitals of this country could not entirely fulfil those functions. It seemed to him that the question—he had no doubt that it was before the Government when they drew up the Bill—was how this hiatus was to be filled up. There was one way in which there could be a considerable extension of a form of coöperative hospital in those homogeneous communities which were increasing in number and were known as garden cities and garden suburbs. There was great scope there for a system of coöperative treatment and for coöperation in matters of health. By linking up these coöperative health societies with the insurance companies there could be a certain solution of the difficulty of hospital provision. Even when that was allowed for there still remained a large gap to be filled. That was why he thought it was proved and a case made out that further hospital provision was needed. In short, it came to this, that all the conditions of to-day tended to move the location of illness from the home to the institution and the need for this hospital accommodation was great. They had to remember, however, that neither the councils nor their medical advisers had had up to now any experience of the curative treatment of disease. If, for example, they took the medical staffs who advised the councils they consisted of medical officers of health and certain people who looked after the clinics. Their experience was limited to their own domain and very excellent work they did; but their experience of curative medicine was little or none; yet they would be called upon under this Bill to fulfil those important functions.

Hospital Organisation.

It must be borne in mind that four-fifths of the medical men of this country were engaged in curative medicine. It was in this respect that he thought that Part I. of the Bill was defective. It seemed to show a lack of appreciation of the essential conditions of success. It was almost as if it said in effect to the Public Assistance Committees: "You can convert your poor-law hospitals if you wish. You can build large hospitals if you wish. I would like you to coöpt a few people who know something about the running of a general hospital, but I will not force you to do so." No doubt some councils would think that anybody could found a hospital. A hospital was not a building made with hands; it was an organisation, an assemblage of great traditions. The hospital service of this country had grown up through the years. Its efficiency, its flexibility of administration, its public spirit, and its warmth of heart had all gathered round what was called the voluntary system. That system had made the hospitals of England famous throughout the world. More than that, these hospitals drew to their service the young man of talent. It was his great ambition to get there. There he worked for years at a pittance in order to gain experience. There he earned his reputation and his discipline. There he got that curious atmosphere of knowledge and service. That was the current of events. That was the recognised road within the profession. Further than that, it was from these hospitals that the nurses came. Was it not obvious that the voluntary hospitals of the country should be made the centre, the kernel round which any new hospital system should be built, and that any legislation should provide that this mode of progress was not only permitted but secured? Surely the correct policy was to foster the voluntary hospital, remembering that it was a very tender plant, and might easily be killed. Let the voluntary hospital lead, let it direct them in building up what he admitted was needed—that was a new and extended hospital policy for the country. The dangers of not doing this were very real. Supposing their was no coöpted minority on these Public Assistance Committees. Supposing, for example, they had a free hand to do what they wished. Supposing (and this was not imagination) a council was returned committed to the policy of a whole-time medical municipal service. That council would set out to build up a service independent of the voluntary hospitals, competing with them and overlapping them, and there was no one to say them nay. That was no mere figment of the imagination. There were at this moment boroughs running, or trying to run, a municipal service. There were certain people who avowed that their object was to set up municipal hospitals and to staff them with a full-time staff and run them as a form of municipalised service. That, surely, would be a disaster. How were they going to get their staff? He presumed they would advertise for it, just as if skilled men like physicians and surgeons grew like gooseberries on a bush. It had already been tried. Advertisement did not bring the right people. It did not secure that round pegs went into round holes, and there had been already consequences which were lamentable, resulting from the wrong people staffing hospitals and doing work for which they were not trained and not suited. That was a very serious danger. If they permitted the councils, whose experience of running curative medicine was up to now small and had almost reached diminishing point, to undertake that new venture without any form of coöption of people who were skilled on the one hand in the administration of hospitals, and on the other hand without any assistance from doctors whose lives were spent in doing the work of curative medicine, there was a very serious danger. He pleaded with the Government to make it compulsory that there should be coöption of a minority on these Public Assistance Committees. It was done in the case of education. If it was sound to do it for education why not do it for health? There was no argument for the one which was not applicable to the other. When the Bill was before the House of Commons the Government had not been able to take a full measure of the opposition to the Bill, and he had no doubt that when they made coöption optional they did it because they did not wish to increase the opposition in the country. But it was surely clear now that the country was in favour of the Bill and there was no longer therefore an excuse for not doing that which all those people who were connected with the administration of public health outside the official world were in favour of doing. The medical profession by practical unanimity had requested that the coöption of the minority skilled in hospital work should be made compulsory, and they appealed very strongly to the Government to concede that point. King Edward's Hospital Fund had taken the same line and on the merits he asked the House whether they would start a new measure and a sound venture, one that might lead to a wide establishment of municipal hospitals for curative medicine in this country and neglect all the traditions and the knowledge that had been gathered during the years.

A Simple Remedy.

There was one other amendment which he would urge on the Government. Up to now the medical staff of the health services of this country had been run by a small number of medical men. They had been men who had specialised in preventive medicine. They had consisted in

the country of medical officers of health, tuberculosis officers, school medical officers, and he would guard himself by saying that there was no one who admired their work more than he did, but it was a work of a strictly limited application. They had never had anything to do with disease. Many of them had never had any contact with hospitals since their student days. How could these men be expected wisely to advise their councils on this large question of curative hospitals? Ever since the Ministry of Health Act was passed it had been a most regrettable fact that the policy of the official doctor—the doctor who was paid by fee, the medical officer of health and the officers he had already noted—proceeded on lines totally divergent from that of those doctors who constituted four-fifths of the profession and who belonged to the curative branch. That divergence was lamentable. It was a serious matter when the council only had to deal with preventive medicine, and it was a still more serious thing if this divergence should continue now—this divergence for which the Ministry of Health had been responsible ever since it was founded. To meet that he suggested quite a simple method which had been before the Ministry of Health for some time, and that was that there should be set up under the chairmanship of the medical officer of health an advisory council of doctors in each district which the council administered. This simple remedy would bring the experience of the men who knew to the benefit of the medical men who had to administer. He believed that the hospital policy in the Bill was capable of great and continued benefit to the community, and if only the Government would accept the safeguards which he had adumbrated in the form of amendments at a later stage they would ensure that the scheme not only brought about reforms, but opened up avenues of progress which would lead to the greater health of the people, in which respect they would fain see this country lead the way.

Further Criticism of the Bill.

Lord THOMSON said that an expert in local government, of 35 years standing, had told him that the Bill was a gamble, that it was based on figures which were guesswork, and that the formula provided a rule-of-thumb, but embodied no principle. The money which would be given to industry was so small in each case that it would not do any good. In his (Lord Thomson's) view the Bill was timorous because it did not attack the central and urgent problem of the necessitous areas.

Lord CRANWORTH said that he welcomed the Bill because it made a first attack on the pernicious tyranny of the percentage grants under which so much public money had been wasted. He believed that, viewed as a whole, the Bill was the best measure brought forward since the war.

Earl RUSSELL said that he must take strong exception to that part of the Bill which dealt with recovering the cost of maintenance of persons in various institutions. It read as if it must be the duty of the local authority to collect the costs to the last farthing, and in Committee the Opposition would endeavour by amendments to soften the harsh character of that proposal. They would also seek to obtain security of tenure for the officials of the local authorities. On the general question of rating relief he said that to give relief to the rich and to put additional burdens on the poor was not the Labour Party's conception of justice. It should not be beyond the wit of man to devise a method which, while giving relief to the individual, did not enrich big firms.

Reply to the Debate.

The Earl of ONSLOW (Paymaster-General), replying to the debate, said that the Bill had not been wholly condemned by any speaker. Lord Beauchamp had complained that the bureaucratic powers of the Minister had been greatly enhanced. But where they had arrangements for the transfer of areas and the adjustment of boundaries, there were found to be disagreements, and it was generally recognised that the only person to whom those disagreements could be referred was the Minister, who was entrusted with the business of local government. Dealing with the criticisms of the purposes for the reform of the poor-law, the noble Earl said that the principle of the Act of Elizabeth had not been really interfered with. The statement had been very freely made that the Bill did not break up the poor-law. The fact was that the Bill dealt with the transfer of the poor-law powers from the guardians to the counties and county boroughs. It did not pretend to break up the poor-law at this time. But it was intended to encourage the break up of the poor-law, and the adoption of the transferred functions under other Acts so far as it was possible. The Bill had been criticised as being too long, and if they had attempted to amend the huge Consolidated Poor Law Act of 1927 the Bill would have been greatly overweighted. Also, any such attempt at present would mean that they would not have the advantage of being able to discuss the amendment of the poor-law with those who were responsible for it, because the guardians, under the Bill, were in a moribund condition, and the counties and county boroughs had not yet come into their inheritance. But it was recognised that the existing poor law and the existing poor-law arrangements must be discussed with a view to reform, and therefore it was proposed to initiate discussions, at a convenient time after the passing of the Bill, with the associations representing the poor-law authorities as to what changes might be necessary in the Act of 1927. Another criticism had been that the Government had not taken unemployment out of the Bill and dealt with it as a national service. But, had they adopted a national system of dealing with the able-bodied unemployed, it would have been impossible to avoid a rigid bureaucratic organisation, with far more hard-and-fast rules than was necessary under the organisation proposed in the Bill, and with an army of officials. Also, it would have been necessary to have two authorities dealing with same people—the national authority dealing with the well and able-bodied, and the local authority dealing with the sick and unemployed. The result of that would have been constant confusion, overlapping, delay, and dissatisfaction. Further, it would be difficult to administer such a service nationally without a return to the principle of the "dole."

The motion for the rejection of the Bill was negatived by 102 votes to 20—majority against, 82.

The Bill was then read a second time.

THE BILL IN COMMITTEE.

On Tuesday, March 5th, the Local Government Bill was considered in Committee, the Earl of DONOUGHMORE in the chair.

Provisions as to the Alternative Powers of Giving Assistance.

The Marquess of READING moved an amendment to Clause 4 providing that in so far as administrative schemes prepared by councils under the clause related to hospitals the councils should take reasonable steps to seek and to continue to secure full coöperation with every voluntary hospital within or serving the area of the council. He strongly urged the Government to accept the amendment.

Lord DAWSON also had an amendment down on the Order paper to the following effect:—

"A council, in preparing a scheme under this section, shall have regard to the desirability of consulting (*a*) any body existing in the area which is so constituted as to be representative of the voluntary hospitals in the area, and (*b*) any body existing in the area which is so constituted as to be representative of the duly-qualified medical practitioners in the area, including those on the medical and surgical staffs of any voluntary hospitals in the area."

The Earl of ONSLOW (Paymaster-General), who represented the Ministry of Health, said that he was prepared to move the following new clause in order to meet the views that had been expressed on behalf of the voluntary hospitals:—

"The council of every county and county borough shall make such arrangements as they think desirable for securing that the functions transferred to them under this Part of this Act with respect to the provision of hospital accommodation will be discharged after consultation with such body, if any, within the county or county borough as they consider to represent the voluntary hospitals in the area."

In the debate which followed the view was expressed that the Government's new clause was too vague in its terms, and it was also criticised on the ground that it did not meet Lord Dawson's point in regard to the consultation of the medical profession in each area.

The Earl of ONSLOW assured the House that it was the wish of the Government to settle the matter in accordance with the desires of the House. He undertook to have the clause redrafted before the Report stage, and he hoped that in its altered form it would be acceptable both to Lord Dawson and to the rest of the House.

The Marquess of READING withdrew his amendment.

Lord DAWSON, in intimating that he would not press his amendment, said he hoped that they would get something more out of the Government.

HOUSE OF COMMONS.

WEDNESDAY, FEB. 27TH.

Sterilisation of the Unfit.

Colonel WEDGWOOD asked the Minister of Health whether he had received a petition signed by many doctors and eugenists, asking for the sterilisation of criminals and mental defectives, and whether the Government intended to take any sort of action in the matter.—Mr. CHAMBERLAIN replied: I have received a resolution urging that an inquiry should be held into the best method of dealing with mental deficiency, including a special inquiry into the possibility and advisability of legalising sterilisation under proper

safeguards and in certain cases. I am not yet in a position to indicate the intentions of the Government in the matter.

THURSDAY, FEB. 28TH.

Workmen's Compensation Statistics.

Mr. TINKER asked the Home Secretary if he was aware that the workmen's compensation statistics presented to Parliament each year did not give a complete list, and that no returns were given from agriculture, road transport, building, and many other industries and occupations; and if he intended to ask Parliament to extend Section 42 of the consolidating Act of 1925 which gave him powers to call for returns from seven great industries, so that all who came under the Workmen's Compensation Act must make returns.—Sir WILLIAM JOYNSON-HICKS replied: Yes, Sir, the present Regulations under Section 42, which require returns to be furnished, do not extend to all industries. The hon. Member will find the reasons for this explained in the Introduction to the Statistics for 1908. The reasons still hold good, but the extension of the Regulations to other industries is noted for consideration as soon as conditions permit. No fresh legislation is required for the purpose.

Scavenging in Rural Areas.

Rear-Admiral BEAMISH asked the Minister of Health whether he would issue an order or introduce legislation to amend Section 42 of the Public Health Act, 1875, to permit of scavenging and cleaning over limited areas of rural parishes and to charge the expenses to that area, and thereby control the growing heaps of insanitary household rubbish which now disfigured so many villages.—Mr. CHAMBERLAIN replied: I have no power to issue an Order for this purpose. The matter has been noted for consideration when an opportunity for legislation arises. I doubt, however, whether legislation would be the most effective cure, and it is likely that improvements would be effected if local authorities would use more freely their influence and their powers.

Health of the Mercantile Marine.

Sir RICHARD LUCE asked the President of the Board of Trade if the necessary sickness and mortality statistics were available or in process of preparation for the use of the joint committee appointed by the Board of Trade and the Ministry of Health to consider matters affecting the health of the mercantile marine.—Commodore KING replied: In addition to the statistics published by the Registrar-General of Births and Deaths there is an annual return published by the Board of Trade of all deaths which occur on ships registered in the United Kingdom. The question whether these statistics can be improved or supplemented is being considered by the Joint Advisory Committee.

Admission of Starved Persons to Hospitals.

Mr. GARDNER asked the Minister of Health whether his attention had been drawn to an account of an inquest at the court of the city coroner, held on Feb. 18th, on a man found by a police constable starved and ill on the pavement outside Holborn Viaduct station; whether he was aware that the man was taken to St. Bartholomew's Hospital because there was an arrangement not to send cases to the City of London poor-law hospital after 9 P.M., and that the man was refused admission and taken elsewhere and there refused and then brought back to St. Bartholomew's, and then put into an isolated room and found dead on the floor at about 1.30 A.M.; by what poor-law authority this arrangement was made and when, and whether it was known to the poor-law inspector or at the Ministry of Health; whether any similar arrangement existed elsewhere and, if so, where; whether he would inform the superintendents or masters of all poor-law hospitals that they must admit all cases of starvation and exposure brought by police officers without any order from the relieving officer; and whether he would revive the lists of starvation cases which were published from about 1870 till 1918.—Mr. CHAMBERLAIN replied: The reply to the first part of the question is in the affirmative. In reply to the second part there is not, and could not legally be, any arrangement preventing the admission of cases to the poor-law infirmary of the city of London Union or any other infirmary during prescribed hours of the night. The arrangement made between the guardians and St. Bartholomew's Hospital is that where a bed is available at the hospital cases shall not be sent on to the infirmary during the night, but shall be kept until the morning and then removed, and this arrangement seems to me a very proper one. If the patient had been sent to the infirmary he would have been admitted, as in fact I am informed that many other persons are admitted both by day and by night. As regards the last part of the question I do not think that any useful purpose would be served by a revival of the returns.

Medical Records in the Army.

Mr. SHEPHERD asked the Secretary of State for War whether there was any trace of rheumatism in the Army medical history of Mr. G. J. Ross, Louisa-street, Darlington, late trumpeter, Royal Artillery.—Mr. DUFF COOPER replied: The medical records of soldiers are confidential documents, and it would be contrary to the established practice to disclose details from them.

Dr. VERNON DAVIES: Does not the hon. gentleman see that in the case of an appeal a person is handicapped if he cannot get any particulars of the medical history of the case? He is placed in an absolutely impossible position.

Mr. COOPER: The previous history is open to the people advising the appellant.

Dr. DAVIES: The hon. gentleman has just indicated that it is not.

The Traffic in Heroin.

Mr. CECIL WILSON asked the Home Secretary whether, seeing that the heroin available for internal consumption in 1924 was 909 kilogrammes, that the manufacture and imports in the following year was 344 kilogrammes, the exports and re-exports 236 kilogrammes, and the weight available for internal consumption 108 kilogrammes, he could explain what became of the balance of 1017 kilogrammes in 1924 and 1925, seeing that this was many times the quantity available for internal consumption in other years.—Sir WILLIAM JOYNSON-HICKS replied: The explanation is that the figures include 745 kilos of heroin in 1924 and 15 kilos of heroin in 1925, which were not used as such, but were reconverted into morphine. If these figures are subtracted from those quoted by the hon. Member as available for internal consumption, it will be found that the balance in each year approximates to the general annual average of the surplus of heroin imported and manufactured over that exported and re-exported. The bulk of the heroin so reconverted consisted of illicit consignments to the Far East which were seized at Hong-Kong and sent home to this country for disposal.

Mr. WILSON: Can the right hon. gentleman say whether the amount of 108 kilogrammes is not in excess of that recommended by the Committee of the League of Nations and that the Chinese coolies do not destroy all the heroin that is seized in this way and whether we are making a profit out of it.

Sir W. JOYNSON-HICKS: The heroin is not destroyed, but is sent over here in order to be utilised for medicinal purposes.

MONDAY, MARCH 4TH.

Protection of Drivers against Exposure.

Mr. SHEPHERD asked the Minister of Transport what regulations prevented the provision on omnibuses, tram cars, taximeter-cabs, and other public vehicles, of adequate protection for their drivers against exposure to the weather.—Colonel ASHLEY replied: There are no general regulations which would prevent the provision on public service vehicles of adequate protection for their drivers against exposure to the weather, but there are, I understand, local regulations made by certain local licensing authorities limiting the use of windscreens on vehicles licensed to ply for hire.

Protection of Civil Population against Poison Gas.

Mr. ROBERT MORRISON asked the Prime Minister whether the scheme which had been prepared for the protection of the civil population against poison gas in future warfare would now be submitted to the local authorities in order that arrangements might be commenced for training the necessary personnel, as had already been done in other countries.—Mr. BALDWIN replied: As I indicated to the hon. Member on Feb. 12th, the problem of the protection of the civil population against gas attack is being closely studied in all its aspects. Further work, however, remains to be done before any scheme can usefully be communicated to the local authorities.

Death at Whipp's Cross Hospital.

Miss LAWRENCE asked the Minister of Health whether his attention had been directed to the circumstances attending the death of Miss Sarah Dicks at Whipp's Cross Hospital; whether he was aware that no communication of the death was made to the relatives of the deceased, a message being sent only to her lodgings; and whether he would cause inquiries to be made.—Sir KINGSLEY WOOD replied: This case was reported to my right hon. friend by the medical superintendent of the hospital. He learns that the case was put on the danger list immediately after admission and was visited by relatives who were informed that they could stay with the patient as long as they chose. The last visit paid by the relatives was within an hour of the patient's death which took place at 8.55 P.M. on Jan. 21st. In accordance with the usual practice of the guardians, which my right hon. friend considers a proper one, the relatives were not informed of the death that night, but notice was sent by special messenger at 8 o'clock on the following morning to the address furnished on the hospital bed-card.

TUESDAY, MARCH 5TH.

Use of Cocaine in Poor-law Institutions.

Mr. DAY asked the Minister of Health whether he had received any complaints of large amounts of cocaine used in any of the poor-law institutions in England and Wales; and if it was his intention to set up an inquiry into these charges.—Sir KINGSLEY WOOD replied: My right hon. friend has received no formal complaint of this kind, but he is aware of one instance in which a poor-law medical officer has used considerable quantities of this drug for his own treatment. The officer has resigned his appointment, and my right hon. friend sees no reason for further action on his part.

Disease Germs in Bombs.

Lieut.-Commander KENWORTHY asked the Secretary of State for War whether the War Office had information to the effect that bombs or shells carrying disease or plague germs were used by the German forces on the Western front during the great war.—Sir L. WORTHINGTON-EVANS replied: No, Sir. The War Office has no other information than that contained in the Official History of the War, Vol. II., Medical Services, Chapter 17.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At a congregation held on March 1st the following degrees were conferred:—

M.B. and B.Chir.—J. A. Hartley and J. D. Procter.
M.B.—A. J. Dix-Perkin.

The Council of the Senate have presented a report on an offer to equip a nutritional laboratory, which has been made by the Medical Research Council through their secretary, Sir Walter Fletcher, and recommend that the offer should be gratefully accepted.

SOCIETY FOR THE STUDY OF INEBRIETY.—At the rooms of the Medical Society of London, 11, Chandos-street, Cavendish-square, W., on Tuesday, April 9th, at 4 P.M., Dr. J. D. Rolleston will open a discussion on Alcohol in Therapeutics.

TUBERCULOSIS OF BONES, JOINTS, AND LYMPH GLANDS.—A course on this subject will be held at the Hôpital Maritime at Berck Plage, Pas de Calais, France, from March 25th to 30th, under the direction of Dr. Etienne Sorel. Information can be got from Dr. Delahaye at the hospital.

THE Minister of Health has expressed his approval of a proposal to invite the International Union of Local Authorities to hold their next congress, which is due to take place in 1932, in this country.

SOFIE NORDHOFF-JUNG PRIZE.—This prize, offered for the best work in recent years on the investigation of cancer, has been awarded to Prof. Katsusaburo Yamagiwa, of Tokyo, for his research on the experimental production of cancer by cutaneous irritation.

A BRITISH SANATORIUM AT MONTANA (SWITZERLAND).—A new sanatorium, known as The British Sanatorium Montana, has recently been opened at this favoured spot high up in the valley of the Rhone by Dr. Hilary Roche, late medical superintendent of the Palace Sanatorium, Montana. The new sanatorium is intended for the reception of British patients only.

FINANCES OF UNIVERSITY COLLEGE HOSPITAL.—A festival dinner took place at the Mansion House last week in support of the appeal for £30,000 to pay off the accumulated debts on this institution, and to provide the nucleus of an adequate reserve. Prince George, the President, who was in the chair, announced at the close of the evening that the entire sum, and a little more, had been obtained.

RESEARCH ON RHEUMATOID ARTHRITIS. — The bequest of £300 to the University of Manchester, under the will of the late Miss Amy Henrietta Worswick, will be devoted in accordance with her wishes to the investigation of the causes and treatment of rheumatoid arthritis. A temporary fellowship of the value of £150 per annum will be offered, and application may be made to the Registrar before Oct. 15th next by any person who has obtained a medical qualification registrable in the United Kingdom.

GENERAL LYING-IN HOSPITAL.—It was stated at the annual meeting last week that among 1043 cases admitted last year there were only three deaths. Under the covenants of the lease the premises have to be rebuilt next year, and £19,500 is still required to meet the cost.

LONDON REFRACTION HOSPITAL.—On Thursday in last week the Countess of Mayo opened the enlarged premises of this hospital in Newington Causeway, S.E. It was originally established in 1922, and in the first year 563 patients were treated; last year the number was nearly 6,000. The institution has been built and equipped by the Institute of Opthalmic Opticians which is now asking for help towards its maintenance, the cost having outgrown the means of the institute.

INSTRUCTION FOR D.P.H.—A three months' course of lectures and demonstrations on clinical practice and in hospital administration will be given at the North-Eastern Hospital, St. Ann's-road, Tottenham, London, N. by Dr. F. H. Thomson, the Medical Superintendent, on Mondays and Wednesdays at 4.45 P.M., and alternate Saturdays at 11 A.M., beginning on Monday, April 8th. Particulars may be had from the Clerk to the Metropolitan Asylums Board, Victoria Embankment, E.C.4.

POST-GRADUATE COURSE AT WEST LONDON HOSPITAL.—A syllabus has been issued of the lectures and demonstrations to be given in connexion with the post-graduate course to be held at the West London Hospital, Hammersmith, from March 11th to 23rd. The course will deal with general medicine, surgery, and the special departments, with special reference to recent advances, and there will be daily sessions from 10.30 A.M. to 5.30 P.M., except on Saturdays, when only the mornings will be occupied. The syllabus is obtainable from the Dean of the Post-graduate Medical College, who should be addressed at the Hospital, Hammersmith, W.6.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—Particulars of lectures and demonstrations during the coming week will be found in our Medical Diary. Fixtures for April include a practitioners' course at the London Temperance Hospital, and courses in tropical medicine at the London School of Hygiene and Tropical Medicine, in electrotherapy at the Royal Free Hospital, in medicine, surgery, and gynæcology at the Royal Waterloo Hospital, and in neurology at the West End Hospital for Nervous Diseases. Copies of all syllabuses, and details of the general course of work in the London hospitals affiliated to the Fellowship may be had from the Secretary at 1, Wimpole-street, W.1.

A DEPUTATION ON PUBLIC HEALTH QUESTIONS.—Mr. Amery (Secretary for Dominion Affairs), Mr. Neville Chamberlain (the Minister of Health), and Mr. Betterton (Parliamentary Secretary to the Ministry of Labour) lately received a deputation from the General Council of the Trades Union Congress. In reply to the suggestion that the possibility of securing reciprocity with the Dominions in social insurance should be placed on the agenda of the next Imperial Conference, Mr. Amery said that apart from the Irish Free State the Dominions had not yet put into force comprehensive schemes for health, pensions, and unemployment insurance on lines corresponding to those in existence in this country, and consequently a scheme of general reciprocity was at present impossible. The matter had been considered by the Imperial Conference in 1926, since when it had been taken up with the Dominion Governments and some progress was being made. A health insurance Bill had been introduced into the last Commonwealth Parliament, and was likely to be reintroduced, and in South Africa a Royal Commission was considering the question of health insurance. He promised that, if the Government were returned to power, the question should be on the agenda of the next Conference. The deputation also submitted resolutions urging the Government to take further measures for dealing with the present housing situation by an extended building programme and the demolition of slum areas, and requesting the Minister of Health to give facilities to insurance committees so that Section 107 of the National Health Insurance Act, 1924, which is directed against bad housing and other conditions, may be made operative. This section enables inquiries to be made into the causes of excessive sickness in particular localities. Stress was also laid on the need for more women sanitary inspectors, the Trades Union Congress having agreed "that at least one whole-time woman sanitary inspector should be appointed on the staff of every metropolitan borough council and on the staff of every local authority administering a large industrial area." Finally a resolution on the abolition of privately owned slaughter-houses was brought forward. In his reply Mr. Chamberlain said that Section 107 of the Insurance Act had not proved workable in practice. The appointment of women sanitary inspectors could not be pressed upon the smaller authorities who employed one sanitary inspector only, but he agreed that in the metropolitan boroughs and other large authorities the appointment of women was desirable. As opportunities occurred he would be prepared to encourage the institution of public slaughter-houses.

KING EDWARD'S HOSPITAL FUND FOR LONDON.—Hospitals within 11 miles of St. Paul's wishing to participate in the grants made by this Fund for 1929 should apply before March 31st to the hon. secretaries of the Fund, at 7, Walbrook, E.C.4. Applications will also be considered from convalescent homes in the above area or those which take a large proportion of patients from London.

DONATIONS AND BEQUESTS.—Mr. Arthur Wheeler Margrett, King's Heath, Birmingham, left on the death of his daughter £1250 to the General Hospital to endow a bed to be called the A. W. Margrett bed; £1000 each to the Royal Society for the Prevention of Cruelty to Animals, Lord Haig's Fund, and the Queen's Hospital, Birmingham; £500 to the Eye Hospital, Birmingham; £250 to the Women's Hospital, Showell Green, Birmingham; and the balance of such proceeds to the Home for Incurables at Putney.—Mr. Walter Richard Haighton Chappel, Great Duryard, Exeter, left about £20,000 to charities, including £2000 to the Princess Elizabeth Orthopædic Hospital, Exeter, for giving children the benefit of sea air; £500 each to the Miners' Hospital at Redruth, the Devon and Exeter Hospital, and the Home for Incurables, Exeter; £250 each to the Camborne District Nursing Association, the Exeter Dispensary, and the Devonshire Nursing Association.—Mr. Morris Marians, Rodney Court, Maida Vale, left £1000 to the Home and Hospital for Jewish Incurables, £500 to the London Hospital for the Jewish Ward, and £250 each to the Jewish Board of Guardians, and the Jews' Hospital and Orphan Asylum.—Mr. William John Fieldhouse, C.B.E., J.P., Austy Manor, Wooton Waven, Warwick, left £500 each to the Children's Hospital, Birmingham; the General Institution for the Blind, Birmingham; the General Hospital, Birmingham; and the Stratford-on-Avon Hospital.

CARDIFF MEDICAL STUDENTS' CLUB (LONDON BRANCH).—This club inaugurated its London branch at a successful dinner held on St. David's Day (March 1st) at Frascati's Restaurant. Dr. Dan Davies presided over a gathering of some 50 former students of the school, who were continuing their clinical studies at various London hospitals owing to the closure of the Cardiff Royal Infirmary to students. The chairman, proposing the toast of Dewi Sant, said that the study of the early history of the University of Wales, its struggles and its successes, could not fail to deepen the patriotism of young Welshmen. The life and work of Viriamu Jones should be familiar to all graduates of the University. Other universities had prospered through benefactions from the rich, but the University of Wales had been built up largely from the contributions of the peasantry. There had been some movement in the large towns of Wales in favour of the establishment of local universities; the breaking up of the Federal University of Wales would, in his view, be a retrograde step. Prof. E. H. Kettle, of St. Bartholomew's Hospital, proposed the Welsh National School of Medicine. He expressed a profound faith in the future of the school and regarded the gathering that evening as a gesture of belief and pride in the school on the part of the younger generation. He had reluctantly been forced to the conclusion that the ideals which had inspired those who had worked for the development of a great national school had been forsaken, and that envy, selfishness, and pettiness of vision had resulted in a real tragedy—the eclipse of the school. He trusted that the eclipse would only be temporary, but it must be remembered that the school could not rise again without financial assistance from the Government, and no money was likely to be forthcoming unless substantial guarantees were given that the deplorable situation of last year would not again arise. Mr. W. D. Lovelock-Jones, in seconding, expressed the sincere hope that Welsh nationalism would demand the resurrection of the school. Prof. A. W. Sheen, responding, said that negotiations were still in progress. The students who had not finished their studies were anxious to return to Cardiff, and he trusted that by next October the school would be re-established. Prof. A. M. Kennedy, who also replied, was less optimistic. He had been impressed by the loyalty of the students in Cardiff to the professors, and would like to see a great Welshman take the position in hand. Mr. E. Llewellyn Williams and Mr. D. C. Harris proposed the health of the professors, and Prof. E. L. Collis replied in g ni l vein. The toast of the Cardiff Medical Students' Club was given by Mr. J. P. G. Howells, Miss M. E. H. Jones seconding Prof. T. Graham Brown, as president of the club, conveyed greetings from the junior students working in Cardiff. Sir Ewen Maclean, when proposing the Guests, referred to the exigence of the requirements of the University of London. It was hardly reasonable to insist, as a condition of recognition, that every member of the hospital staff should accept responsibility for teaching. The final toast of the Chairman, proposed by Mr. Lambert Rogers, was acclaimed with musical honours.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, March 11th.—5 P.M., WAR. Paper: Surg.-Commdr. Horace Hill, R.N.: Post-encephalitis and its Problems in the Service.

TUESDAY.—5 P.M., THERAPEUTICS. Communication: Dr. G. Linder and Dr. C. F. Harris: Treatment of Chronic Tetany with Steatorrhœa in Adults. 4.30 P.M., PSYCHIATRY. (Tea will be provided at 4 P.M.) Clinical Meeting at the Maudsley Hospital, Denmark Hill, S.E. Cases will be shown illustrating Neuroses and Psychoses of Childhood.

THURSDAY.—5 P.M., BALNEOLOGY. Paper: Dr. J. F. Halls Dally: The Spas of Switzerland. Discussion on Diathesis in Arthritis. Opener: Dr. H. A. Ellis. To be followed by Dr. E. P. Poulton and Dr. E. Obermer. 8.30 P.M., NEUROLOGY. Cinematograph Demonstration of a film showing work on "conditioned reflexes" in Prof. Pavlov's Laboratory, Leningrad. N.B.—Admission will be by ticket only. Applications for tickets should be addressed to the Secretary, Royal Society of Medicine.

FRIDAY.—8 P.M., OBSTETRICS. Joint Meeting with the Maternity and Child Welfare Group of the Society of Medical Officers of Health. Discussion on the Future of the Maternity Services. Openers for the Section of Obstetrics: Prof. J. M. Munro Kerr, Mr. Eardley Holland. Openers for the Society of Medical Officers of Health: Dr. Eustace Hill (M.O.H., Co. Durham), Dr. J. J. Buchan (M.O.H., Bradford). 8.30 P.M., ELECTRO-THERAPEUTICS. Paper and Demonstration: Dr. W. S. Whitcombe: Intensive Ionisation. Paper: Dr. A. B. MacLean (Glasgow): The Prone Position as a Routine Method in the X Ray Examination of the Stomach, with a note on the question of Retractability of the Stomach. (Illustrated by lantern slides.)

BIOCHEMICAL SOCIETY.

FRIDAY, March 15th.—4.30 P.M. (in the Department of Physiology and Biochemistry, University College, Gower-street, W.C.). Communications: I. Smedley MacLean: Further Observations on the Sterols of Yeast. H. J. Channon and A. C. Chibnall: The Isolation of N-Nonacosane and Di-n-Tetradecyl Ketone from Cabbage Fat. J. G. Davis and A. T. R. Mattick: The Metabolism of a Pigmenting Anaerobic Bacterium. G. N. Richardson and R. K. Cannan: Reaction of Azine Compounds with Proteolytic Enzymes. B. C. Guha and J. C. Drummond: Observations on the Concentration of Vitamin B1. J. C. Drummond, R. A. Morton, and K. H. Coward: A Critical Examination of the Methods for the Assay of Vitamin A. C. R. Harington and S. S. Randall: Isolation of 3:5-Diiodotyrosine from the Thyroid Gland.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, March 11th.—8.30 P.M., Discussion on the Chronic Dyspepsias of Children over the Age of Infancy. To be introduced by Dr. R. Miller, followed by W. G. Wyllie.

HARVEIAN SOCIETY, Town Hall, Paddington Green.

THURSDAY, March 14th.—8.30 P.M., Dr. E. Graham Little: The Medical Profession, the Voluntary Hospitals, and the De-rating Bill. (Harveian Lecture.)

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.

TUESDAY, March 12th.—5 P.M., Prof. E. B. Verney: Polyuria. (Second Goulstonian Lecture.)

THURSDAY.—5 P.M., Prof. E. B. Verney: (Last Goulstonian Lecture).

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

MONDAY, March 11th.—5 P.M., Mr. C. E. Shattock: Specimens Illustrating Disease of the Kidneys.

FRIDAY.—Prof. Sir Arthur Keith: Recent Advances in Our Knowledge of the Anatomy and Physiology of the Gall-bladder.

NATIONAL HOSPITAL, Queen-square, W.C.

MONDAY, March 11th.—12 noon, Dr. Greenfield: Pathology of Nervous System. 2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Kinnier Wilson: Some Disorders of Sleep.

TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Martin: Disorders of Sensation.

THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Bailey: Muscular Paresis and its Electrical Treatment.

FRIDAY.—12 noon, Dr. Martin: Anatomy and Physiology of Nervous System. 2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Dr. Symonds: Neurological Complications of Acute Specific Fevers.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE. (Intensive Course, First Week, 10.30 A.M. to 5.30 P.M.)

MONDAY, March 11th.—Dr. Harold Pritchard: Processes of Excretion, with special reference to the Renal Function. Mr. Donald Armour: Head Injuries (Lecture I.) Sir Henry Simson: Meddlesome Midwifery. Dr. H. E. Archer: The Chemical Investigation of Pancreatic and Hepatic Function. Dr. J. Burnford: Glycosuria.

TUESDAY.—Dr. M. E. Shaw: Peptic Ulcer. Dr. Grainger Stewart: The Diagnosis of Intracranial Tumours. Mr. Tyrrell Gray; Surgical Ward Cases. Mr. Sangster Simmonds: The Treatment of Injuries, illustrated by cases (Lecture I.). Dr. Scott Pinchin: The Use of Artificial Pneumothorax and Lipiodol in the Diagnosis and Treatment of Pulmonary Disease (Lecture I.).

WEDNESDAY.—Dr. Carter Braine: X Ray Therapy (case demonstration). Mr. Neil Sinclair: Demonstration of Surgical Cases. Mr. O. L. Addison: Diagnosis of Tumours of the Breast. Dr. Redvers Ironside: Clinical Demonstration on Endocrine and Metabolic Disorders (Demonstration 1). Mr. Sangster Simmonds: Demonstration of Splints Used in the Modern Treatment of Fractures.

THURSDAY.—Dr. S. A. Owen: Diseases of the New Born, including Intracranial and other injuries, Hæmorrhage, Jaundice, Heart Disease. Mr. Donald Armour: Head Injuries (Lecture II.). Mr. Vlasto: Vertigo. Mr. Bishop Harman: The Three "Pink Eyes," Conjunctivitis, Iritis, and Glaucoma. Mr. S. G. MacDonald: Urological Problems (Lecture I.).

FRIDAY.—Dr. Scott Pinchin: The Use of Artificial Pneumothorax and Lipiodol in the Diagnosis and Treatment of Pulmonary Disease (Lecture II.). Dr. G. B. Dowling: Protein Sensitisation in Relation to Skin Diseases (First Lecture: Urticaria). Dr. Harold Pritchard: The Advantages and Indications for Intravenous Methods of Treatment. Dr. Redvers Ironside: Clinical Demonstration on Endocrine and Metabolic Disorders (Demonstration 2). Mr. F. C. Endean: The Modern Treatment of Syphilis.

SATURDAY.—Dr. R. R. Elworthy: Laboratory Values (Lecture I.). Mr. F. St. J. Steadman: Oral Sepsis in Relation to General Disease.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, March 11th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases Clinics. Operations.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W.

MONDAY, March 11th, to SATURDAY, March 16th.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. Mon., at 5 P.M., Lecture by Dr. F. W. Price: Pitfalls in Cardiology.—WELLCOME MUSEUM OF MEDICAL SCIENCE, 33, Gordon-street, W.C. Wed., at 4 P.M., Demonstration by Dr. W. J. O'Donovan: The Treatment of Skin Diseases by Light Therapy, Indications and Limitations.—ROYAL NATIONAL ORTHOPÆDIC HOSPITAL, 234, Great Portland-street, W. Thurs., at 11 A.M., Clinical Demonstration by Mr. S. L. Higgs.—THE INFANTS HOSPITAL, Vincent-square, S.W. Thurs., at 4 P.M., Dr. Eric Pritchard: A clinical demonstration of cases illustrative of the difficulties arising in connexion with digestive disturbances in infants. The above are free.—ROYAL NATIONAL ORTHOPÆDIC HOSPITAL, 234, Great Portland-street, W. All-day course.—ROYAL EYE HOSPITAL, Southwark, S.E. Afternoon course. Further particulars from the Secretary.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, Endsleigh-gardens, W.C.

MONDAY, March 11th, and TUESDAY and WEDNESDAY.—5.30 P.M., Prof. F. Fülleborn: Some Questions of Tropical and Local Helminthology.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, March 12th.—3.15 P.M., Mr. J. B. Hunter: Appendicitis.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, March 14th.—4 P.M., Dr. Poynton: On Virus Diseases.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, March 12th.—5 P.M., Dr. J. E. M. Wigley: Leukæmia Cutis, Mycosis Fungoides.

THURSDAY.—5 P.M., Dr. J. E. M. Wigley: Pemphigus and Allied Eruptions.

UNIVERSITY COLLEGE, Gower-street, W.C.

MONDAY, March 11th.—5 P.M., Mr. P. Eggleton: The Chemistry of Muscle Contraction.

NATIONAL COUNCIL FOR MENTAL HYGIENE, 78, Chandos House, Palmer-street, S.W.

WEDNESDAY, March 13th.—5 P.M. (at the Medical Society of London, Chandos-street, W.), Sir Maurice Craig: The Problem of Nervous Breakdown.

ANCOATS HOSPITAL, POST-GRADUATE LECTURES, Mill-street, Manchester.

THURSDAY, March 14th.—4.15 P.M., Mr. Harry Platt: Sciatica.

MEDICAL SCHOOL, Leeds.

WEDNESDAY, March 13th.—3.30 P.M., Mr. Cecil Rowntree: Cancer and the General Practitioner.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.

FRIDAY, March 15th.—3.30 P.M. (at the Royal Hospital), Mr. F. Wilson: Clinical Cases.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, March 12th.—4.15 P.M., Dr. C. H. Melland: The Use and Abuse of Aids to Diagnosis.

FRIDAY.—4.15 P.M., Mr. C. Roberts: Demonstration of Surgical Cases.

Appointments.

WITTS, L. J., M.D. Manch., has been appointed Fifth Assistant Physician to Guy's Hospital.

Certifying Surgeons under the Factory and Workshop Acts: MILNE, C. I., M.D., Ch.B. Edin. (Hanley, Stafford); WHYTE, VENABLES, H. A., M.B., B.Chir. Camb. (Pulborough, Sussex).

Vacancies.

For further information refer to the advertisement columns.

All Saints' Hospital for Genito-Urinary Diseases, 91, Finchley-road, N.W.—H.S. At rate of £100 to £150.

Ashton-under-Lyne, District Infirmary.—Res. Surg. O. At rate of £200.

Barrow-in-Furness, North Lonsdale Hospital.—H. S. £150.

Bath, Royal United Hospital.—H.S. Also Asst. H.S. At rate of £150 and £100 respectively.

Bedford, Bedfordshire Sanatorium.—Res. Asst. M.O. £400.

Bedfordshire County Council.—Asst. M.O. £600. Also Asst. County Dentist. £450.

Birmingham, Ear and Throat Hospital.—2nd and 3rd. H.S. Each at rate of £150.

Birmingham General Hospital.—Surg. Cas. O. £400.

Brentwood Mental Hospital.—Jun. Asst. M.O. £510.

Bristol City Mental Hospital.—Third Asst. M.O. £300.

Cambridge, Addenbrooke's Hospital.—H.S. At rate of £130.

Cancer Hospital, Fulham-road, S.W.—Anæsthetist.

Cardiff, City Mental Hospital, Whitchurch.—Research Chemist. £800.

Cardiff, North Wales Sanatorium, Llangwyfan, near Denbigh.—Third Asst. Res. M.O. £250.

Chester, East Lancs. Tuberculosis Colony, Barrowmore Hall, Great Barrow.—Asst. M.O. £250.

City of London Maternity Hospital, City-road, E.C.—Asst. Res. M.O. At rate of £80.

Coventry and Warwickshire Hospital.—Res. H.P. £125.

Croydon, Mayday-road Hospital.—Res. Asst. M.O. £300.

Derby, Derbyshire County Sanatorium, near Chesterfield.—Res. Asst. M.O. £350.

Dreadnought Hospital, Greenwich, S E.—H.P. and H.S. Each at rate of £110.

Dudley, Guest Hospital and Eye Infirmary.—Asst. H.S. £150.

Durham County Council and Chester-le-Street Urban District Council.—District Tuberculosis M.O. and M.O.H. £700.

Eastbourne, Princess Alice Memorial Hospital.—Jun. H.S. At rate of £100 to £150.

Gloucester, Gloucestershire Royal Infirmary.—Second H.S. At rate of £100.

Grimsby County Borough.—Asst. School M.O. £600.

Hastings, Royal East Sussex Hospital.—Pathologist. £200. Also M.O. to V.D. Department, £375. Also Hon. Asst. Physician.

Hospital for Sick Children, Great Ormond-street, W.C.—Part-time Jun. Cas. O. At rate of £150. Also H.S. and H.P. At rate of £100.

Hostel of St. Luke, 14, Fitzroy-square, W.—Res. M.O. £200.

Isleworth, Warkworth House Institution and Scattered Homes.—Asst. Med. Supt. &c., £450.

Kensington, Fulham and Chelsea General Hospital, 194, Fin-borough-road, S.W.—Hon. Phy. for Dis. of Skin.

L.C.C. Mental Hospital Service.—Eighth Asst. M.O. £300.

Malayan Medical Service.—Bacteriologist, £700.

Manchester, Salford Royal Hospital.—H.S. to Orthopædic Dept. Also H.S. Each at rate of £125.

Manchester, St. Mary's Hospitals.—Four H.S.'s. Each at rate of £50.

Manchester Babies Hospital, Burnage-lane, Levenshulme.—Jun. Res. M.O. At rate of £50.

Metropolitan Ear, Nose and Throat Hospital, Fitzroy-square, W.—H.S. £150.

Miller General Hospital, Greenwich-road, S.E.—Hon. Asst. Dental S. 30 gns.

National Hospital for Diseases of the Heart, Westmoreland-street, W.—Res. M.O. At rate of £150.

Prince of Wales's General Hospital, Tottenham, N.—Hon. Anæsthetist. £20. Also Hon. Dermatologist.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Asst. Res. M.O. At rate of £80 to £100.

Richmond, Surrey Royal Hospital.—Sen. H.S. Also Jun. H.S. At rate of £150 and £100 respectively.

Royal Free Hospital, Gray's Inn-road, W.—Cas. Officer. £150.

Royal National Orthopædic Hospital, 234, Great Portland-street, W. Hon. Asst. S.

Royal Northern Hospital, Holloway, N.—H.P. Also Obstetric H.S. Each at rate of £70.
Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Hon. Surgical Registrar.
St. Thomas's Hospital, S.E.—Asst. Surgeon in Orthopædic Dept.
Salisbury General Infirmary.—Two H.S.'s. Each £150.
Salop County Council.—Asst. M.O. £600.
Sheffield Royal Infirmary.—Hon. Asst. Surg.
Swansea Hospital.—H.S. £150.
Walsall General Hospital.—Sen. H.S. Also Jun. H.S. At rate of £200 and £100 respectively.
West London Hospital, Hammersmith, W.—H.P. Two H.S.'s. Each at rate of £100. Also Non-Res. House Officer. £5 5*s.* weekly. Hon. Asst. Anæsthetists.
Western Ophthalmic Hospital, Marylebone, N.W.—Sen. and Jun. H.S.'s. At rate of £150 and £100 respectively.
Western Skin Hospital, 44, Hampstead-road, N.W.—Hon. Asst. Dermatologist.
Worksop, Victoria Hospital.—H.S. At rate of £170.

The Chief Inspector of Factories announces the following vacant appointments for Certifying Factory Surgeons :—Hereford Market Deeping (Lincs.), Kinross, Tredegar (Mon.).

Births, Marriages, and Deaths.

BIRTHS.

BRETTELL.—On Feb. 24th, at Heath-terrace, West Bromwich, Staffs, the wife of Harry Macduff Brettell, L.D.S., of a daughter.

MARRIAGES.

CRADDOCK—JOYCE.—On March 2nd, at St. Mary's, Paddington, Stuart Craddock, M.B., B.S., M.R.C.S., L.R.C.P., to Lilian Margaret Meath Joyce.
RYAN—RICKARDS.—On Feb. 28th, at St. James's, Spanish-place, W., Joseph Ernest Noel Ryan, T.D., M.D., to Dulcie, only daughter of the late Lionel E. Rickards.

DEATHS.

BURTON.—On March 3rd, at Lee Park Lodge, Blackheath, S.E., Herbert Campbell Burton, L.R.C.P., M.R.C.S.
CRASTER.—On Feb. 27th, at Keston House, Keston, Kent, Herbert Vaughan Craster, L.R.C.P., L.R.C.S.
EVILL.—On March 3rd, at Warwick-gardens, Worthing, Dr. Frederick Claude Evill, of The Lodge, High Barnet.
HILL.—On Feb. 27th, at Granta, Upper Bassett, Southampton, Alex Hill, M.A., M.D., F.R.C.S., F.R.C.P.
MACKENZIE.—On March 2nd, at Upper Brook-street, Sir Hector W. G. Mackenzie, M.A., F.R.C.P., aged 72.
TURNER.—On March 2nd, at Bury-road, Alverstoke, Hants, Robert Turner, late Deputy Inspector-General of Hospitals, Royal Navy.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

LEEDS WORKPEOPLES' HOSPITAL FUND.—Last year this fund raised £44,560, the largest sum on record. There are 144,000 contributors, and the workshop collections amounted to £36,495. The Leeds General Infirmary, to which £23,677 has been allocated, issued five million doses of medicine to out-patients in the course of the year.

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the Case Committee 40 applications were considered and 36 grants were voted amounting to £744 3*s.* The following is a résumé of four cases :—

Daughter, aged 46, of M.D. Left penniless on the death of her father, and in spite of delicate health, trained as a nurse. She broke down badly after working at a hospital during the war, and though she bravely attempted to resume work later, was ultimately forced to give it up. She is now suffering from tuberculosis. There is no relation who can help. The Fund voted £36 towards the sanatorium fees, and with this as a start a gentleman who knows and admires this lady's uphill fight throughout her life is personally endeavouring to raise a special fund so that treatment in the sanatorium can be continued.

Daughter, aged 25, of L.R.C.P. Is suffering from tuberculosis and every hope is held out of a cure by immediate treatment. The applicant, however, has no private means to enable her to do this. Fund voted £25, and with the coöperation of the Guild enough money has been raised for one year's treatment.

Widow, aged 57, of M.R.C.S. Her husband died in January, 1929, having been mentally deranged for the last years of his life. During these years his wife had had to attend her husband, and on his death such little income they had, amounting to £117 per annum, ceased. Her brother is able to contribute £26 per annum. Being an energetic and capable woman it is hoped that after she has had time to recover her health, which has been badly broken by all she has had to suffer, she will be able to find work and fend for herself. To give her the necessary rest and opportunity to find work the Fund voted £28 towards her maintenance.

Widow, aged 60, of M.B., whose husband died in November, 1928. After everything is settled and debts are paid the income which she may hope to receive from her husband's estate will be 15*s.* a week. Voted £30 in four instalments. Her total income will then be only £69 a year, but she hopes she may find some lodgers to take into her home and thus augment her ncome.

Notes, Comments, and Abstracts.

THE EFFECTS OF MUSIC UPON THE HUMAN BLOOD PRESSURE.

BY SWALE VINCENT, M.D. LOND., D.SC. EDIN., LL.D.,
PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF LONDON;
AND
J. H. THOMPSON, B.SC.,
DEMONSTRATOR IN THE DEPARTMENT OF PHYSIOLOGY, MIDDLESEX HOSPITAL MEDICAL SCHOOL.
(*From the Department of Physiology, Middlesex Hospital.*)

THE effects of music upon the human organism have naturally received a certain amount of attention, but comparatively few exact observations have been made upon the circulatory system.

In 1914, Vincent, Cameron, and Armes [1] contributed to the Royal Society of Canada a paper upon the effects of music upon the blood pressure, and reported certain changes as measured with a Rogers's sphygmomanometer. They employed simple tones (single notes, scales, arpeggi) as well as more elaborate pieces of music. The latter consisted of piano pieces by various composers, songs with piano accompaniment rendered by amateur and professional performers, and various compositions played by a full symphony orchestra. They classified their subjects into three groups : (*a*) musical, (*b*) moderately musical, (*c*) non-musical. In a musical person they found that the effect of a quiet uneventful composition is a steady lowering of the blood pressure, but they recognised that this might be largely a rest effect. When the music was of greater interest and possessed a liveliness dependent on rapid movement, intensity of tone, discords, sudden changes of key, &c., they usually obtained rises of blood pressure. They also found that if the music was of such a kind as to arrest severely the attention of a musical individual, the effect might be a fall, and this they thought was the result of altered respiration. They found that singing produces less effect than piano-playing, and that the effect of a full orchestra is not different from a piece played on a piano, except that the nature of the composition would be different in the two cases. With moderately musical and non-musical people they found that the principal difficulty is to find compositions which to them will be of sufficient interest to produce any effect. These observers thought it possible that there is a relation between the reaction time and the impressionability to music, and they discussed the action of musical stimuli in producing changes of blood pressure.

In general, they concluded that musical interest would give a rise of blood pressure, whilst absence of such interest would be without effect. It will be seen that these do not quite coincide with our present results.

Method of Observation.

During the past few months we have been employing an instrument of which preliminary descriptions have been given [2] for recording various influences upon the human blood pressure. Briefly, the Thompson sphygmanograph consists of a modified water manometer connected to a special armlet whereby it becomes possible to record variations in blood pressure over long periods of time without causing any discomfort to the subject.* It was obviously a matter of great interest to experiment with musical stimuli and to compare the results with those obtained by the older methods.

There is another difference between our experiments and those of Vincent and his earlier co-workers. While the latter employed " real " music, we have confined our attention to the effects of reproduced music. This is a matter of some importance, as such music is much commoner than in 1914, and large numbers of people listen to very little else in a musical direction.

We have to express our best thanks to the Marconiphone Co., for the use of a super 8-valve wireless receiver ; to the Gramophone Co. for the use of " His Master's Voice " gramophone model No. 202 and a large selection of records ; and to the Columbia Gramophone Co. for some interesting records.

There are many reasons for supposing that the results produced in a concert room are likely to be very different from those brought about by listening to a gramophone

[1] By means of specially constructed armlets it is now possible to record over unlimited periods of time without causing venous congestion. The effects of muscular movements upon the pressure system have been also eliminated.

or a wireless loud-speaker. There is naturally an excitement of a special kind which must accrue when one is in the actual presence of the performers and the rest of the audience. We venture to suggest also that, since there is so much more music at the present date than in 1914, people have become to a certain extent immune to its effect. This is corroborated by the observation that, with some notable exceptions, professional musicians are not as much affected by music as musical amateurs. The best type of subject is undoubtedly a musical amateur of good taste and emotional susceptibility, who can, and habitually does, enjoy music in a naïve manner without the exercise of too much critical faculty.

Then, of course, there are corresponding difficulties with the type of music selected for the experiment. It is not to be expected, for example, that a musically sophisticated person will be roused to any very great emotion by the rendering of a Strauss waltz, even if he hears it direct from Vienna! On the other hand, it is not much use to try Holst's "Planets" on a gentleman who can go into raptures over "The More we are Together."

The actual volume of sound which reaches the ears is obviously a matter of great importance. We are unable to state at the present time whether, when one sits near to a full-sized gramophone and hears an orchestral reproduction, the volume of sound and degree of stimulation are greater or are less than when hearing the same composition in the Queen's Hall. There seems to be no readily available method of measuring volume of sound.

We have made every effort to surmount these difficulties, and we have, we think, obtained some results which are of interest.

We have found that it is essential that the subject should remain seated in a comfortable position for some few minutes before listening to the music. During this period there is a slight fall of blood pressure in perhaps the majority of subjects, and in a small number a slight rise. The actual result will depend upon the degree of the preliminary activity or excitement. In the present series of experiments we have not found that increase of emotional effect is necessarily concomitant with a rise of blood pressure. It seems to be the case that sometimes there will be a rise and sometimes a fall, and either one or other of these occur, whatever was the initial height of the original blood pressure.

Experiments Involving the Use of a Wireless Receiving Set.

The receiving set and operator were shielded from the subject's view by a screen, and the loud-speaker placed about six feet behind the subject. Many of the experiments were spoilt by morse, "atmospherics," and impulses from electrical machines in the neighbourhood. All such experiments were discounted for the purpose of this investigation, since the subjects were unable to concentrate their attention upon the actual music. Only those experiments in which music reproduction was good and without interruption have been used in the analysis of the results.

Wireless Results.

—	Musical group.	Moderately musical group (m.m.g.).	Non-musical group.
Volume	No effects.	Increase of volume = { interest—fall. no interest—rise.	Same as m.m.g.
Melody	Fall.	Slight fall.	No effect.
Pitch	—	High pitch = { interest—rise. no interest—fall.	—
Rhythm	—	Slight fall.	? Rise.
Beginning	Rise.	—	Rise.

Musical Subjects.—It was found that with musical subjects volume changes produced small effects upon the blood pressure. It was possible to vary artificially the volume within a very considerable range, and also to produce loud and sudden noises, but in no case did the variation in volume cause any marked disturbance of blood pressure in this group. In striking contrast, however, were the effects obtained by changes in melody and rhythm, particularly melody. In some instances it was possible to gauge the emotional content of the music by means of the blood pressure tracing! A change from an "amorphous" type of music to a melody pleasing to the subject almost invariably was accompanied by a marked fall in blood pressure. The same phenomenon was noted when a pleasant melody occurred several times in the same piece. Similar results of less degree occurred with changes of rhythm.

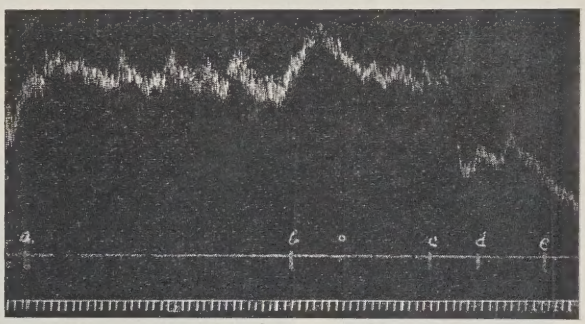
The chief characteristic of this group is a fall of blood pressure. The only occasion when small rises of blood pressure were obtained was at the commencement of the music. That this was an effect due to the music is verified by the control experiments in which "musical" subjects submitted to a "rest" experiment as above described. All such subjects gave slow gradual falls of blood pressure commencing at the onset of the experiment. Anticipation of the music by the subject can also be excluded because "dummy" experiments gave results identical with "rest" experiments.

It was impossible to analyse the effects of appreciation * of the music heard by these persons because not one of the ten members of the group fully appreciated any musical item of the experiments. In all cases the "unreality" of reproduced music appeared to antagonise appreciation. Symphonic music gave the greatest falls of blood pressure, chamber music slight falls, dance music was without effect, and military bands (which came through very well) showed small rises. Symphony music, therefore, conformed most to the characteristic effect of this group.

Moderately Musical Group.—Onset of music caused small rises in blood pressure and cessation was coincident with a corresponding fall. The fall at the conclusion was most marked when the music was full of interest to the subject. Volume effects were obtained with all subjects in this group. The effects were well-defined. When the music was not interesting, increase of volume caused a fall of blood pressure, and decrease of volume a rise of blood pressure. When interest in the music was taken, increase of volume produced a rise of blood pressure, and decrease of volume a fall of blood pressure (Fig. 1).

A unique characteristic of this group as compared with the other two groups was the effects of the pitch of the music. Again, this factor and interest were co-related. When the music was not interesting a high-pitched note, or series of notes, brought about a fall in blood pressure, whilst the same notes when there was full interest, caused a rise of blood pressure. Changes in melody and rhythm showed variations in blood pressure comparable to those obtained in the musical group, although they were much smaller. The general effect upon the blood pressure was therefore very small in this group, although the tracings were markedly irregular, due to fluctuation in interest, volume, and pitch. Chamber music and dance music showed little general effect, symphonic music resulted in continued rises of blood pressure, whilst singing caused marked falls. Chamber music in particular exhibited the type of tracing most often obtained from this group.

FIG. 1.



Effect of volume on moderately musical subject: (A) commencement, (B) increased volume, (C) decreased volume, (D) increasing volume, and (E) end.

Non-Musical Group.—Detailed changes in the music were practically without effect in this group of individuals. Volume changes were slight, and were of the same type as those in the "moderately musical" group. Pitch and melody failed to produce any characteristic changes in blood pressure. There were marked initial rises of blood pressure, but no terminal effects were observable. In nearly all cases, however, there was a steady rise of mean blood pressure throughout the experiment. All the eleven subjects in this group were interested keenly in "wireless," and possibly it was this interest in the reception which caused the continued rise of blood pressure. Control experiments failed to show such rises.

Symphonic music produced slight falls of blood pressure, chamber music and singing showed either slight falls or were without effect, and dance music invariably gave considerable and continued rises of blood pressure. Dance music thus becomes the type of music which most easily elicits the characteristic blood-pressure record of this group.

* "Appreciation" is used to mean an intelligent comprehension of the aims of the composer, and an enjoyment of the total effect produced.

Experiments Involving the Use of a Gramophone.

The experiments involving the use of a gramophone were conducted under conditions identical with the last series of experiments. For the purposes of analysis, subjects were again divided into the three groups—musical, moderately musical, and non-musical. A large number of persons were examined, and owing to the large selection of records kindly lent to us, it was possible to try the effects of various types of musical composition upon each person.

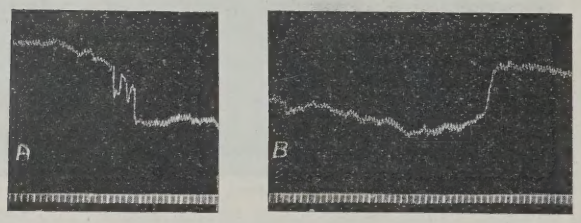
Gramophone Results.

—	Musical group.	Moderately musical group.	Non-musical group.
Volume	Loud = fall. Soft = no rise.	Loud = small fall. Soft = no rise.	No effect.
Melody	Rise.	Slight rise.	,,
Pitch	High pitch = rise.	Change to high pitch = small rise.	,,
Rhythm	—	Increase = rise. Decrease = fall.	Fall in one subject.
Beginning	Fall.	—	—

Musical Group.—The reactions of subjects in this group were very well marked. The variations in blood pressure were considerable and frequent whenever the music was of the type which was appreciated by these subjects—namely, the "classical" type.†

The majority of people exhibited a marked fall of blood pressure coincident with the commencement of music, except in the case of vocal music, when the fall was replaced by a rise (Fig. 2). Conclusion of music resulted in a slow recovery process. Members of this group were very

FIG. 2.



A = Commencement of instrumental music showing depressor effect in a musical subject.
B = Commencement of vocal music showing pressor effect in the same subject.

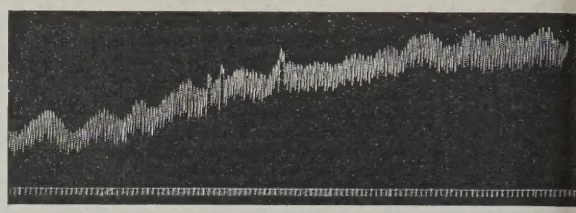
responsive to all kinds of differences in the music, provided there was appreciation. Volume effects were always present, loud tones producing considerable and immediate falls of blood pressure. A striking feature of this group was the rapidity of response, the latent period being much smaller than in the other two groups.

Careful analysis of a large number of experiments has shown that whereas loud tones produce falls of blood pressure, soft tones do not cause rises of blood pressure. Soft tones allow recovery from a previous fall due to increased volume to take place, but no rise above the original mean occurs although the decreased volume persists. It seems reasonable to infer, therefore, that mere volume of sound causes depressor effects which become increasingly obvious as the volume increases. Usually, of course, many other factors mark this effect by superposition. Thus, in this particular group, changes in melody were potent means of varying the blood pressure. Changes in melody such as occur in Beethoven's "Moonlight Sonata," caused rises of blood pressure in subjects of this group, and these rises were largest when the melody was played softly (Fig. 3). The fact that rises were invariable with melodies appreciated by the subjects even when rendered fortissimo is indicative of the greater potency of melody as compared with volume.

Differences in pitch also showed effects. That these effects were caused by contrast is shown by the many experiments in which transition from a very low pitch to a high one, and vice versa, were coincident with a rise and fall of blood pressure respectively. But maintenance of notes of high pitch did not cause a progressive rise of blood pressure, nor did notes of low pitch produce a fall of blood pressure. Effects due to pitch were largely swamped by volume effects. Thus large falls were recorded, when the pitch fell with increasing volume but under similar conditions with decreasing volume, the above-mentioned recovery process still occurred although somewhat more gradually.

In relation to the kinds of music used in these experiments it is interesting to note that all members of this group gave rises of blood pressure with vocal music. Even the initial fall characteristic of this group was superseded by a rise of blood pressure where vocal music started at the beginning of the experiment. When there were a few preliminary bars of instrumental music the usual fall occurred, but was

FIG. 3.



Continued rise of blood pressure in a musical subject whilst listening to Beethoven's "Moonlight Sonata."

immediately checked and a rise began when singing commenced. It is interesting to note that the solo flute appears to have a similar effect. Symphonic music and good chamber music elicited most response, whilst dance music gave very little variation in the tracing.

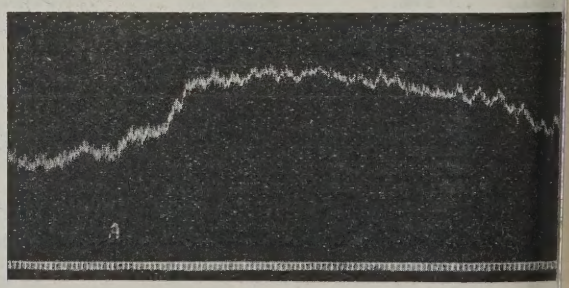
The general effect upon the blood pressure in this group was a fall of blood pressure. A small minority of subjects showed a higher pressure at the end than at the beginning. It is to be noted that all the persons were of an emotional type, and were easily excited by music. Thus, in one instance, the subject became pallid, developed muscular twitchings, and showed signs of intense emotional excitement when listening to the second part of the overture to "Oberon" by Weber.

Previous knowledge of the piece of music does not appear to alter the results in any way. The determining factor is appreciation. So long as the subject appreciates the music played, so long do all the above-mentioned phenomena occur. Non-appreciation always results in a slow gradual fall without variations.

Moderately Musical Group.—Subjects in this group were like members of the previous group, very responsive when the music was appreciated. But "appreciation" in this group really means "interest" when applied to this group—that is to say, it was necessary in order that effects could be produced for the subject to derive definite pleasurable interest from the music, rather than to find an intellectual appreciation therein. Consequently we encountered the same difficulty as Vincent and Cameron—namely, finding music compositions of sufficient interest to produce any effect.

Volume, pitch, and melody exerted an influence comparable to that in the musical group, but in lesser degree.

FIG. 4.



Showing the effect of the substitution (A) of comic opera (Gilbert and Sullivan) for pianoforte music upon a moderately musical subject.

Moreover, rhythm showed well-marked results. Increased rhythm caused a rise of blood pressure, and decreased rhythm a fall, other factors remaining constant. Rhythm swamped volume and pitch, but was subservient to melody.

Symphonic music produced chiefly slow unvaried falls and dance music had little effect apart from rhythm and association. Popular music like Gilbert and Sullivan comic operas gave best results (Fig. 4). Such music had little influence with the musical subjects, but with members of this group the detailed variations of blood pressure were

† The word "classical" is not used here in its strictest sense, but (in accordance with popular usage) simply means music which is considered worthy of attention by competent musicians.

as pronounced as those obtained in the musical group with symphonic music. There was one notable difference, however—commencement of music was coincident with a rise of blood pressure.

Non-musical Group.—Although a large number of subjects were examined in this group, in not a single instance was a rise of blood obtained. The general effect was a slow uneventful fall of blood pressure commencing with the onset of music and continuing for a short while after cessation of music. Lively and unusual music provoked a smaller gradient fall, whilst quiet melodious music, particularly pianoforte, elicited more rapid falls.

One subject was included in this group who entirely failed to be interested in any kind of music except "jazz." His pleasure in hearing "jazz" was probably not a musical emotion at all. The effect of a foxtrot well-known to him was to cause a large and sudden fall of pressure which was augmented by the predominance of the saxophone part. After the experiment he described his keen enjoyment of the music by the expression: "I could hardly keep still and wanted to dance."

Discussion.

From a purely musical standpoint, the wireless experiments upon the musical and non-musical groups must be discarded, since in the former group there was complete absence of appreciation, and in the latter group the effects were mainly due to an interest in the wireless reception itself. There was true musical interest and some appreciation in the moderately musical group in both sets of experiments, and it will be observed that the results obtained are remarkably similar. In both series these subjects showed initial rises, with variations corresponding to melody, rhythm, pitch, and volume, the volume effects being dependent upon appreciation of music.

The most well-defined and greatest effects are always obtained with members of the musical group when the music is of a kind they are able to appreciate. The more nearly "real" the music is, the more obvious are these results. Hence, in this particular investigation, there was more response with the gramophone than the wireless when applied to the musical subjects. Conversely, the smallest variations of blood pressure occur in the non-musical group. As already stated, the characteristic rise shown by this group whilst listening to music reproduced by a loud-speaker is probably due to interest in the wireless, since substitution of the loud-speaker for a gramophone causes the characteristic of the groups to become a fall of blood pressure.

The predominant factor is appreciation or interest, and not the type of music, as seems to be imagined by most workers. For example, J. D. Hyde [3] concludes that Tschaikowsky's "Symphonie Pathétique" unfavourably affects listeners by lowering the blood pressure, &c. But our investigations clearly demonstrate that the moderately musical person who appreciates the symphony experiences a rise of blood pressure. Volume, too, is a most important factor. If the symphony be played very loudly the rise may be converted into a slight fall, or at any rate the rise will be diminished.

Helda Eng [4] has tabulated many results according to appreciation or not. Records of the respiration were taken during the experiments, and in all the experiments variations in depth and rate of respiration were found. Vincent and Thompson [5] have shown that in all subjects with pulse-rates above 65 per minute that increased respiration is coincident with falls of blood pressure. Further experiments alone recently have also demonstrated that diminished respiration causes slight rises of blood pressure. In view of these results it is significant that in all instances in which Helda Eng obtained falls of blood pressure she also obtained increased respiration, and conversely with rises of blood pressure diminished respiration.

We also have recorded respiration during the foregoing experiments and found that occasionally the respiration was affected, and was the cause of some of the variations of blood pressure. All such results have been eliminated and only those used for analysis which showed no alteration in the respiratory record. When marked respiratory variations occur they are nearly always coincident with obvious emotional excitement. The greater the emotional stress the more marked are these variations.

A. S. Warthin [6] obtained very large differences, both in rate and depth in respiration, when he tried the effect of music upon hypnotised subjects.

We have to express our thanks to Dr. Agnes Savill for some references to literature, and for providing subjects for experiments.

Summary.

Continuous records of human blood pressure have been taken showing the effects of reproduced music upon it.

Subjects were grouped into three sets—musical, moderately musical, and non-musical. Each group was found to respond differently in relation to variations of volume, melody, rhythm, pitch, and type of music.

Intelligent comprehension of, and interest in, the music were important determining factors in the first two groups. Melody produced the most marked effects in the musical group, while volume effects were most apparent in the moderately musical subjects.‡

BANISTERIN OR HARMINE?

Messrs. Burroughs Wellcome and Co. call our attention to claims made at the Berlin Medical Society by Profs. Lewin and Schuster for a new drug called "banisterin," considered to be "a cure against paralysis caused by organic brain diseases." Prof. Lewin has described "banisterin" in two papers (*Archiv für experimentelle Pathologie und Pharmakologie*, 1928, cxxix., 133, and *Comptes rendus de l'Académie des Sciences*, 1928, clxxxvi., 469) and the composition and chemical characters of the alkaloid are so like those of harmine, discovered by Fritsch in 1847, as to leave little doubt in the minds of chemists that "banisterin" is harmine. Prof. Lewin remarks that this has been suggested to him, but he follows his brief description of the pharmacological action of "banisterin," in the second paper mentioned above, with the remark "To my knowledge harmine does not produce similar effects." In the *Archiv* paper he states he is relying on published information regarding the action of harmine.

Harmine is available in England, if not in Germany, and Messrs. Burroughs Wellcome and Co. regard it as essential that a pharmacological comparison of "banisterin" and harmine should be instituted as soon as possible. The point is important, because if Prof. Lewin's results are confirmed a demand may arise for this drug, and harmine can probably be made much more easily from the usual source, the seeds of *Peganum harmala*, than from the plant utilised by Prof. Lewin, *Banisteria caapi*. The latter is one of the suggested sources of the "yage" used by South American Indians as a narcotic. "Yage" has been repeatedly examined and the two most recent papers on the subject (Elger: *Helvetica Chimica Acta*, 1928, xi., 162, and O. Wolfes and K. Rumpf: *Archiv der Pharmazie*, 1928, cclxvi., 188) leave no doubt that the alkaloid it contains is harmine, though it was at first mistaken for a new alkaloid and called "yageine" by Villalba. Moreover Wolfes and Rumpf state that Prof. Lewin obtained his alkaloid from the same plant material as they did. The remarkable properties ascribed to "yage" are reflected in the name "telepathine," which Bayon gave to an alkaloid he obtained from "yage" and which is probably also harmine.

THE SCIENCE OF LIFE.

WE have received from the Amalgamated Press, Ltd. (Farringdon-street, London, E.C. 4), the first part of a serial entitled "The Science of Life," which is to be completed in about 30 fortnightly issues. The object of the publication is to present in a clear and readable form a complete and fully illustrated survey of biological knowledge. The joint authors are Mr. H. G. Wells, his son Mr. George Philip Wells, and Mr. Julian Huxley, who not long ago surrendered his chair of zoology at King's College, London, in order to set himself free for the work of popularising biological knowledge. Mr. Wells is now attempting to do for biology what he has done for history, and in a way "The Science of Life" may be regarded as supplementary to the "Outline of History" on the wider basis of the whole animal and vegetable kingdom. A week ago in the leading columns of *Nature* it was stated that the average citizen is not intensely interested in the biological nature of his own existence. Prof. Huxley's grandfather was convinced that the problems of life must one day be investigated by the methods of physical science if biological speculation is not to degenerate into a barren debate, and this survey should help in a really important way to interest the reading population of this country in biology. Should it be possible thus to educate parents we may then hope that the almost complete neglect of biology in the school curriculum will be made good, and that qualified men and women will be found to teach biology in the same way as formal physics and chemistry are now taught in the public and other secondary schools. The first instalment of the survey will be on sale to-day (March 7th) at 1*s.* 3*d.* of all booksellers.

‡ It is more than probable that harmony and orchestral scoring ("colour") played their part, but we have not been able to separate these factors.

DISTRICT NURSING AND INSURANCE COMPANIES.

AT the annual meeting on Feb. 28th of the Central Council for District Nursing in London, the report of the Council for the year 1928 was presented. During the past year the Council has been successful in extending and consolidating district nursing work in and near London, notably in Wandsworth, Bermondsey, Hammersmith, Sunbury, and Willesden, and the inauguration of a service for the new London County Council "Watling Estate" falling within the Hendon Urban District is projected.

During the year three nurses have benefited by the midwifery bursaries of £35 granted by the trustees of the London Parochial Charities. At the instance of the orthopædic registrar of Guy's Hospital, the executive committee has arranged with affiliated district nurses associations for the nursing of club foot in young children. Nurses will attend the massage department in order to be instructed in the particular manipulation necessary for the work. Special courses in the nursing of ophthalmia neonatorum have also been arranged by some associations. The need for organising the nursing of pemphigus has also been considered, and a list of instructions used by the Queen's and Ranyard nurses was circulated to other district nursing associations.

The committee have carefully considered the subject of district nursing in connexion with industrial insurance companies. The inclusion of nursing service for policy-holders of certain insurance companies has made the matter one of immediate concern to all district nursing bodies. One insurance company in some districts employs its own nurses, while in many others it contracts with the district nursing associations to attend its policy-holders on agreed terms. It is reported that the paid canvassers of the company compete with the voluntary canvassers of some of the district nursing associations, and that an extension of the provision of nursing by insurance companies is probable. The Council note that the provision of district nursing by profit-earning companies is said to be common in the United States, and one American company is extending its operations to this country.

They express regret at a development of district nursing which brings it into association with commercial bodies seeking to make a profit. In their view such association conflicts with the voluntary principle on which the work had hitherto been conducted; moreover, the association might possibly lead to a reduction in subscriptions. No objection can be taken to insurance companies providing nursing services for their policy-holders, but there is a difference of opinion as to whether or not it is desirable that this provision should be made by employing the nurses of the existing district nursing associations.

A further question has been raised as to the fee which district nursing associations should expect insurance companies to pay for each visit. Approved societies pay 1*s.* 4*d.* The cost of a district nurse's visit cannot readily be ascertained for the whole of London, but it is generally considered that 1*s.* 4*d.* is less than the average actual cost.

The total awards made to district nursing associations in 1928 amounted to £4443 4*s.* 3*d.*, which included £750 from the Appeal Fund.

THE TREATMENT OF TRACHOMA.

DURING the past 2000 years trachoma has gone under many names, including aspritudo, lips, bleary eye, miliary ophthalmia, and Egyptian ophthalmia. Though the claims of Noguchi to have discovered the causal bacillus have not been confirmed, the disease is admittedly due to infection by a specific micro-organism. The principal reason why it passes from the acute to the chronic stage is ignorance and neglect on the part of those afflicted. Hence it rarely remains in a simple form, and in fact it may be said not to exist without corneal pannus and ulceration.

Dr. Antonio d'Angelo [1] has recently published cases showing excellent results by a method of treatment with organic copper preparations which is somewhat novel in its application and detail. Small quantities of copper can, of course, be found normally in the human body, and when it is administered by mouth to animals and man in very small doses it does not produce any phenomena of intolerance but seems to have the virtues of a hæmogenic reconstituent. Nevertheless, its administration by mouth is not always advisable, while on the other hand intravenous injections are followed by symptoms of intoxication and even death. The objection to local application of inorganic copper salts to the eyes is the pain caused thereby.

Prof. d'Angelo uses in the treatment of trachoma intramuscular injections of cupriodase—a preparation invented by Serono—and a double oleate of copper and cholesterol. The latter can be instilled in a few drops under the tarsal conjunctiva and diffused by gentle massage with the eyelid closed, every ten days, while the cupriodase is given daily by intramuscular injection. From the details given of 24 cases of patients described as "discharged owing to blindness," "almost blind," and with "corneal pannus with only perception of light," and after treatment shown to the Ophthalmic Congress in Palermo as "completely cured," there should be something in this method of treatment deserving of consideration and further trial.

OCULAR SENSATIONS AND "SEA-SICKNESS."

To the Editor of THE LANCET.

SIR,—The following case is probably an instance of ocular sensations being a factor in the production of "sea-sickness." A boy of some 15 years sat facing the engine in a crowded carriage from Newhaven to London. Soon after the start he became very sick and continued to be so every few seconds for quite a long time, until it occurred to me to suggest to his father, who was very anxious about him, that a change of seat might do some good. I gave mine, a back-to-engine seat, to the sufferer, whose sickness ceased instantly and gave place to an immediate sense of comfort and well-being. The suggestion was empirical, but a line of reasoning came in its train. The boy had not been sick on the boat from Dieppe, but his sense organs had been sensitised thereby so as to react in special circumstances, and the ocular reflex was set up when the eye was, so to speak, "running into" its impressions in the misty atmosphere which prevailed.

I am, Sir, yours faithfully,

University College, Cork, Feb. 28th, 1929. D. T. BARRY.

AIRCRAFT IN THE SERVICE OF HEALTH.

ON May 14th there will open in Paris the First International Congress on the use of aircraft in health services (aviation sanitaire). It will be presided over by Marshal Lyautey and Prof. Charles Richet, supported by Dr. Chassaing, General Lévy (Director of Health Services at the Ministry of War), and the president and vice-president of the Ligue Aéronautique de France. The scientific programme is an arduous one; it comprises the work of the aeronautical health service in warfare abroad, in the colonies and at sea, as a means of evacuation in wartime; the question of the immunity from attack of health service machines; the physiological conditions of air transport; the treatment of sick and wounded transported by air; the work of the service in peace-time and the material used. Visitors to the Congress will find much to interest them when their more serious work is over. An exhibition of aeroplanes will be held at the Villeneuve-Orby aerodrome where the machines will carry out extensive demonstrations, and the Congress will visit Rheims and be entertained by the Aero Club of the Champagne district. Particulars may be obtained from the Secrétariat-Général, 35, Rue François-Ier, Paris.

THE RECEDING CHIN.

THE strong silent hero with jutting-out chin had bes enjoy his popularity while he may. His knell was sounde a dozen years ago by Sir Arthur Keith and Prof. F. Woo Jones, who pointed out that the chin is a very recen acquisition, depending on the recession of the jaw resultin from the use of the hands and the kitchen to prepare foo for digestion. The alveolar margin has receded more quickl than the lower part of the mandible; hence the chin o which we are so proud. It is only a matter of time, the think, before the rest of the jaw will fade away too, and ou profile will run sadly from nose to neck. Mr. G. B. Palme has returned to this subject in a recent article [1] and confirm the work of previous investigators. Comparison of th outlines of the mandibles of eoanthropus, Heidelber Neanderthal, and modern man shows a steady reductio of alveolar length. If modern man and eoanthropus b superimposed with the third molar in alignment, the incisor of the modern will barely reach as far forward as the secon premolar of his ancestor. Already eoanthropus has lo many of the features of a typical jawful of teeth, adapted t fighting, seizing the prey, tearing it up and masticating i His canine has begun to come into line with the incisor- though it is still rather larger—and he has no "snout. With the perfection of cooking, man is reverting to th infantile type of mastication—pressing the food against th palate with the tongue and swallowing it. Soon—in th evolutionary sense, quite soon—man will dispense wi teeth altogether, his alveolus will degenerate entirely, as senility, and most probably his mandible will follow su So, at any rate, anthropologists think. It is for mode popular health movements to attack the culinary art the name of health and beauty.

Goulstonian Lectures

ON

POLYURIA

Delivered before the Royal College of Physicians of London

BY ERNEST BASIL VERNEY, M.B. CAMB., F.R.C.P. LOND.,

PROFESSOR OF PHARMACOLOGY IN THE UNIVERSITY OF LONDON, UNIVERSITY COLLEGE.

LECTURE I.—POLYURIA ASSOCIATED WITH PITUITARY DYSFUNCTION.

(Delivered on March 7th, 1929.)

MR. PRESIDENT AND FELLOWS,—In my first lecture I should like to deal with the nature and ætiology of the polyuria associated with disturbance in the function of the pituitary body; in my second, with the nature of the polyuria which follows experimental reduction of the renal tissue and with the mechanism of the production of this polyuria; and in my third lecture I propose to offer some remarks which I hope may be of service in the interpretation of pathological polyuria in man in terms of the findings and theories of experimental physiology.

POLYURIA FOLLOWING ISOLATION OF THE MAMMALIAN KIDNEY.

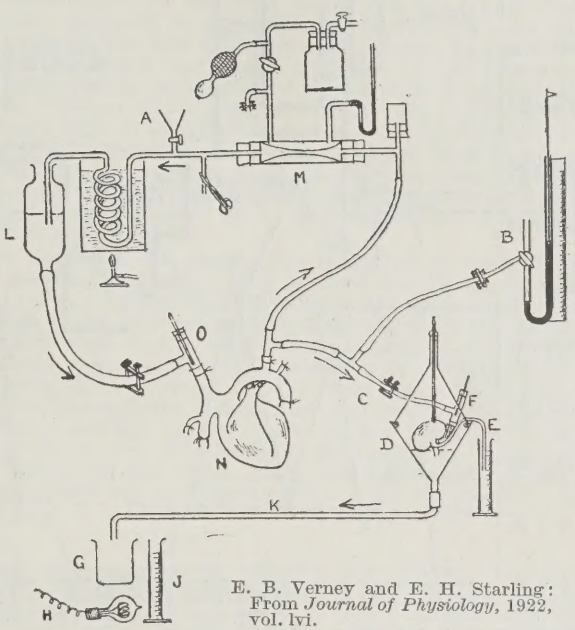
The heart-lung preparation of my inspiring teacher, the late Prof. Starling,[14] not only made possible the discovery by him of the nature of the response by cardiac muscle to changes in the work which it was called upon to perform, with the consequent formulation of this discovery into the law of the heart and its subsequent extension into a clear definition of cardiac tone, but also afforded a means whereby mammalian tissues might be perfused with oxygenated blood under rigidly controllable conditions, and their responses to measurable changes in their environment determined with accuracy.

The isolated kidney of the dog was first perfused by means of a heart-lung preparation by Bainbridge and Evans.[2] They were concerned primarily with the gaseous metabolism of the kidney, and obtained only a minimal amount of urine, and this only on the addition of sodium sulphate or Ringer's fluid to the circulating blood. In 1921 Prof. Starling and I started an investigation into secretion by the isolated kidney,[21] and since the basis of most of the experimental work to which I shall refer in these lectures has been the heart-lung-kidney preparation, a preliminary description of this preparation becomes essential in order that the results obtained by its use may be assessed in their true physiological tenour. All the operative work in the experiments described in these lectures was performed on dogs fully anæsthetised with chloralose, following chloroform and ether induction. The preparation is shown diagrammatically in Fig. 1 and its description is given briefly in the legend.

The advantages of such a preparation in the study of the mechanism of the secretion of urine are evident. The pressure at which the blood is supplied to the kidney, the temperature of this blood, and its content of gaseous and other solutes are directly under our control. The flow of blood and of urine can be accurately measured at any time, and samples of these fluids readily collected in quantities permitting an accurate chemical analysis. It may be said at once that the urine secreted by a kidney so perfused differs in very marked degree, both in quantity and chemical composition, from that secreted by a dog's kidney denervated, but remaining in situ. These differences will be referred to in a moment, but before describing them it is expedient to consider to what extent, if any, these observed changes are due to the development in the blood of some change of state or composition of no physiological, as distinct from toxicological, significance.

Freshly defibrinated blood has been used as the perfusate, but that the specific characters of the urine secreted by the isolated kidney are due to the employment of such blood has been readily disproved by defibrinating the intact animal.[17] If such be done, the urine secreted by the kidneys in situ retains its normal characteristics. Further, in a few experiments with the heart-lung-kidney preparation the anticoagulant heparin has been employed, instead of resort being made to defibrination; the abnormal characters of the urine are still in evidence. These facts suggest that the abnormality observed in the secretion of the kidney, when isolated and perfused with the heart-lung preparation, is to be attributed to some deficiency in its mechanism rather than to the intrusion of some new and foreign activity—a suggestion to which, as we shall see later, experiment lends a concrete significance.

FIG. 1.



E. B. Verney and E. H. Starling: From *Journal of Physiology*, 1922, vol. lvi.

Diagram of heart-lung-kidney preparation. The blood in the venous reservoir L passes through a cannula O, tied into the superior vena cava, to the right auricle. After passing through the lungs, the blood is pumped by the left ventricle through a cannula tied into the brachiocephalic artery to a variable resistance M, whence it returns through a warming coil to the venous reservoir. The tube C conducts arterial blood to a cannula F tied into the renal artery of the kidney D. The venous blood from the kidney is conducted to a vessel G, and returned at intervals to the venous reservoir L. The pressure of the blood-supply to the kidney is recorded by a mercury manometer B. The cannula E is placed in the ureter and the urine collected in a graduated vessel as shown. The cannulæ O and F are provided with thermometers.

The urine secreted by the isolated kidney is clear, yellowish in tint, and gradually pales as the experiment proceeds. Protein is absent, or present in the merest trace, and then only in the first few samples collected. It contains chloride in a much lower concentration than the serum, urea, and sulphate (when this last is added to the blood) in a higher concentration, and is free from glucose. The molybdate test for phosphate is negative, and ammonia is present only in the first few cubic centimetres of the secreted fluid. The total molecular concentration as determined by the depression of the freezing-point is far below that of the serum. The rate of urine flow is abnormally rapid, 1 to 2 c.cm. per minute, for example, being a rate which is quite commonly encountered. The urine, then, is a copious and dilute one, and I should

like to give especial emphasis to its low content in chloride, and to the fact that the typical characteristics of the urine do not suddenly appear at the very beginning of an experiment; they gradually intrude into the picture, and gain in definition as the experiment proceeds.

Verney and Starling: Ref. as Fig. 1.
This experiment demonstrates the urine flow responses of the isolated kidney to changes in perfusion pressure.

To what causes are these curious changes to be attributed? For curious they are when we remember that any increase in the rate of urine elimination by the kidney in situ in the experimental animal is typically accompanied by an approach in the composition of the urine towards that of the plasma. If the urine contain a higher percentage of chloride than the plasma, then an increase in the output of water, produced, for example, by section of the sympathetic supply to the kidney, will be accompanied by a fall in the percentage content of the urine in chloride. If, on the other hand, the urine contain a lower percentage of chloride than the plasma, then the diuresis following sympathetic section will exhibit a percentile rise in the urinary chloride, in each case the diuretic response being attended by an approximation of the chemical composition of the urine towards that of the plasma. But that the normal responses of the kidney to such changes in environment as are produced, for example, by variations in arterial blood pressure, are still exhibited when the organ is perfused in the isolated state, is readily shown by the results of such an experiment as that represented in Fig. 2. It will be seen that the rate of urine flow varies with, and in the same sense as, the height of the arterial blood pressure, and that the concentration of urea in the urine shows an inverse relationship to the rate of urinary flow. And in the case of chloride which, as we have seen, is present in the urine in such low concentration, a percentile rise accompanies the increase in urinary flow produced by an increase in the perfusion pressure. Pressure diuresis, then, as produced in the isolated kidney, gives rise to such changes in the composition of the urine as our knowledge of the reactions of the kidney in situ would lead us to expect—viz., a movement towards the composition of the protein-free plasma. And whether such a change is accompanied by a percentile rise, as in the case of chloride, or by a percentile fall, as in the case of urea, the minute output of each substance secreted is increased during a diuresis provoked by a rise in perfusion pressure.

The ingravescent polyuria of the heart-lung-kidney preparation, being accompanied at constant perfusion pressure by a recession of the chloride concentration of the urine from that of the plasma, and by a fall in the amount of chloride eliminated per unit interval of time, cannot therefore be explained on any hypothesis embodying the conception of a progressive increase in the susceptibility of the kidney to the pressure stimulus. Neither are the observed changes due to acapnia. In the early experiments performed by Prof. Starling and myself,[21] the lungs were ventilated with air and the CO_2 content of the blood fell to a very low level. The fact that prolonged hyperpnœa in man may give rise to a marked polyuria (Collip and Backus[5]), accompanied by a fall in the percentage of urinary chloride (Davies, Haldane, and Peskett[8]), suggested that acapnia might be the cause of the secretory abnormalities observed in the case of the isolated kidney. This suggestion was shown to have no basis in fact, since ventilation of the lungs with air containing CO_2 in as high a concentration as 11 per cent. had no inhibitory effect on the development of the polyuria and the concomitant fall in urinary chloride.[17] Many attempts were made to break down this chloride retention by raising the chloride concentration in the serum to a level higher than the abnormally high one which the retention itself was causing, but all were unsuccessful in attaining this object.

We now suspected that an explanation might be found in the disappearance from the blood of some body which was normally concerned in regulating the output of water and chloride by the kidney. Von den Velden [22] was responsible for the discovery that the polyuria of diabetes insipidus in man could be controlled by subcutaneous injections of extract of the posterior lobe of the pituitary body, and since the urine obtained from the isolated kidney of the dog resembled in its composition that typical of this condition, it was decided to explore the possibility of the two conditions having a common ætiological basis. Pituitary extract was therefore introduced into the circulating blood of a heart-lung-kidney preparation. The polyuria was inhibited in a dramatic fashion, and analysis of the urine showed that the chloride precentage had risen to so high a figure that the minute output of chloride was markedly increased. The data of an experiment which illustrates these facts are collected in the following table. Such changes in water and percentile chloride output invariably occurred, whilst every other means adopted to decrease the urine flow, such as lowering of the blood pressure or the addition of adrenalin, failed to bring about that rise in the urinary chloride which is now believed to be a specific effect of pituitary extract.

We must now inquire whether this action of pituitary extract on the isolated kidney is of any physiological significance in relation to the activity of the normal kidney. Does the pituitary body, through the intermediation of an internal secretion, continually hold in check those primitive instincts in the kidney which, when given rein to, result in its reversion to the type of gland characteristic of the fish and amphibian classes of the vertebrate phylum? In such animals the power to secrete a urine having a greater total molecular concentration, and, in the case of chloride, a greater partial molecular concentration than that of the plasma, is absent; and it may well be that our egress from the sea was accompanied by a demand for an increased degree of control over the salt-and-water metabolism of our bodies, a demand which was responded to by a functional reassociation of those parts which in the higher invertebrates were both engaged in excretory work. For on Gaskell's view of vertebrate development the pituitary body is the homologue of the coxal glands of the crustacea.

Starling and Verney: From Proc. Roy. Soc. B., 1925, vol. xcvii.

This experiment demonstrates the effect of pituitrin on the polyuria of the isolated kidney and on the composition of the urine which it secretes. The pituitrin used was a 0·05 per cent. extract of the dried posterior lobe of ox gland.

Some experiments were therefore undertaken of such a nature as possibly to give an answer to this question.[19] If it be a fact that the polyuria which gradually appears when the isolated kidney is perfused is due to the gradual disappearance of the internal secretion of the pituitary body from the blood, it might be expected that the passage of some of the blood of the heart-lung-kidney preparation through the head of a dog would result in the blood becoming recharged with pituitrin, and so lead to an inhibition of the rate of urine secretion by the isolated organ. This expectation was fulfilled as the result of some experiments to which reference will now be briefly made.

A heart-lung-kidney is prepared and the effect on the quantity and composition of the urine of switching various parts of the tissue of another dog into perfusion-parallel with the kidney is observed. By the term perfusion-parallel is to be understood the diversion of some of the blood from the arterial side of the heart-lung to the particular tissue perfused, the efferent blood from this tissue being led back to the venous side of the heart-lung, and so reaching eventually the isolated kidney, also connected with the arterial side of the heart-lung preparation. The isolated kidney is, therefore, used as a test object by means of which the blood passing through it may be biologically assayed as to its content in pituitrin-like substances. Four series of experiments were performed. In the first series the head and neck were perfused in parallel with the kidney; in the second series the hind legs and pelvis; in the third the head and neck after exposure of the pituitary body, and in the fourth the head and neck subsequent to removal of the pituitary body. The main artery and vein, to and from the part to be perfused, were carefully isolated and included within loose ligatures in such a manner that the appropriate cannulæ could be inserted at the desired moment, and the perfusion started with the minimum period of circulatory arrest.

In Fig. 3 are charted the results of an experiment of the first series. The gradual rise in the output of water by the isolated kidney and the concomitant fall in the percentage of chloride in the urine in the early part of the experiment are clearly seen. The temperature of the blood supplied to the kidney, the hæmoglobin content of this blood, the rate of blood flow through the kidney, and the pressure of supply, are recorded at the head of the figure. At the point G, by which time the polyuria was well developed, the head, neck, and right forelimb were switched into perfusion-parallel with the kidney. It

F, Urinary chloride (as NaCl) in mg. per cent.

will be seen that this procedure evoked a marked and ingravescent fall in the urinary flow, accompanied by an equally well-marked and ingravescent rise in the percentage of chloride in the urine. Indeed, in this experiment there was actually a rise in the absolute amount of chloride during the period G to H, as compared with that excreted immediately before switching the head into the circuit. At H the head and neck were switched out of the circuit, and it is seen that after a short period of time the polyuria returned, and the urinary chloride began to fall again. Further, it is to be noted that a small diminution in renal blood flow resulted from the passage of the blood through the head of the animal, followed by a recovery during the second polyuria. The blood pressure at the renal cannula was constant throughout the main part of the experiment. Such an experiment, which is illustrative of the results obtained in this series of investigations, proves conclusively that the blood of the heart-lung-kidney preparation, when perfused through the head and neck of another animal, picks up some substance which reacts on the kidney in a manner qualitatively indistinguishable from that of pituitrin.

The second series of experiments was designed to control those which have just been described. It may be said at once that perfusion of the pelvis and hind limbs of a dog in parallel with the isolated kidney has no detectable influence on the polyuria and low chloride output of this organ. On the other hand, the results already described as accruing from the perfusion of the head and neck in parallel with the kidney appear in their entirety when the pituitary body is exposed by temporal decompression. If, however, the pituitary body is first removed and the experiment then proceeded with, the isolated kidney is completely unaffected, as far as my observations go, by the passage of the blood of the heart-lung-kidney preparation through the head. In such an experiment we see a profuse polyuria appearing in the animal from which the pituitary body has been removed. It is clear that the appearance of the polyuria in the animal which is intact except in so far as the pituitary body is concerned, is closely related with the persistence of the polyuria of the isolated kidney during the time that the head of the animal is being perfused. The results of an experiment which illustrates these facts are given in Fig. 4. In this experiment the pituitary body was exposed through the temporal route and the urine collected from each ureter until sufficient for purposes of analysis had accumulated. At the point F in the figure the temporal lobe was gently elevated, the pituitary body freed from its connexion to the base of the pituitary fossa and removed with long forceps. Occasionally in such experiments the body—anterior and posterior lobes—came away cleanly in one piece and the removal was, as far as could be determined with the naked eye, complete. More frequently, however, the body was removed in fragments. Hæmorrhage was very slight, a fact which is doubtless to be correlated with the rapid and profuse branching into vessels of almost capillary calibre of the sheaf of vessels streaming down from the circle of Willis around the stalk of the hypophysis (Dandy and Goetsch).[7] The operations both of exposure and removal were performed under direct illumination from a frontal lamp, so that stereoscopic vision was not interfered with.

It will be seen from the figure that removal of the pituitary body was followed, after a latent period of about 50 minutes, by an ingravescently profuse polyuria and by a concomitant fall in the percentage of chloride in the urine. These acute effects of pituitary removal will be considered later. At present it suffices to note the occurrence, and to state that the resultant polyuria and low chloride percentage respond to intravenous injections of pituitrin in a manner exactly analogous to that of the polyuria and low urinary chloride encountered with the isolated kidney.

After the polyuria had become well established, the chest was opened, and the animal prepared for heart-perfusion. A heart-lung-kidney preparation was then made. The urine flow and urinary chloride of the isolated kidney are charted to the right of the figure. At G the head and neck of the polyuric animal were switched in parallel with the isolated kidney. There was a small and quite transient fall in the urine flow, which then rapidly mounted again to reach the large value of over 2 c.cm. per minute. The urinary chloride showed no appreciable brake in its rate of fall nor was there any diminution in the blood flow through the kidney resulting from the passage of the blood through the head of the animal. At H the head and neck were switched out of the circuit. That the absence of any demonstrable effect

At F the pituitary body was removed from the intact dog. At G the head, neck, and right fore-limb were switched into perfusion parallel with the isolated kidney, and at H were switched out of the circuit. At K 0·02 c.cm. "Infundin" was added to the blood perfusing the isolated kidney, and at L a further 0·01 c.cm. was added.

on the isolated kidney, of the passage of the blood of the preparation through the head of the dog was due to the lack of the pituitary hormone and not to any insusceptibility of the isolated kidney to the pituitary stimulus, was shown by the addition of pituitrin to the blood at the points K and L. The typical response to pituitrin is immediately made manifest.

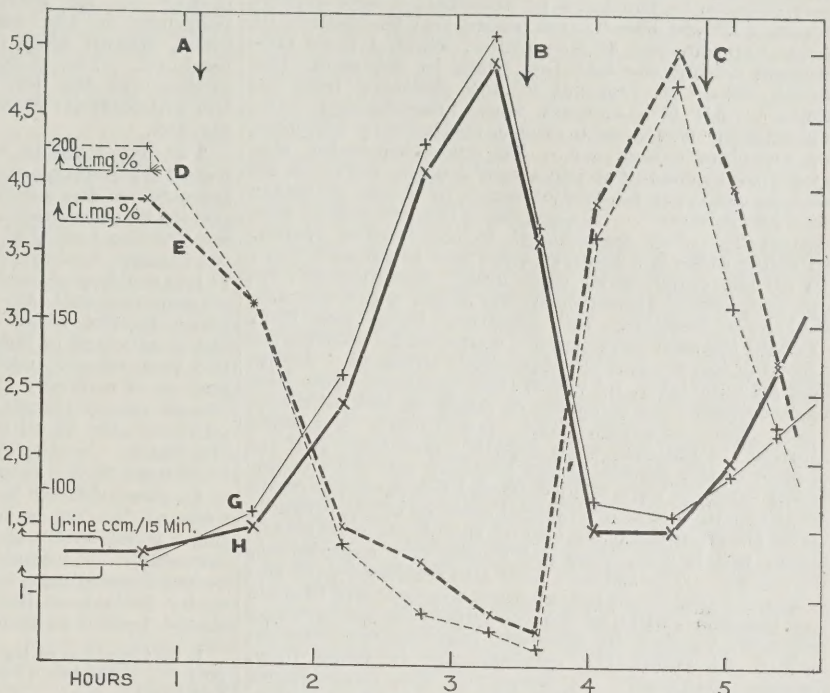
There seems to be only one interpretation to be placed on the experimental results which have just been recorded: pituitrin is contributed by the pituitary body to the blood during its passage through the head and neck. Attention may be directed especially to the ingravescent manner in which the reaction of the isolated kidney reveals itself during the period of head perfusion, a phenomenon which is readily interpreted by, and indeed is to be expected from, the increasing number of circuits which the blood makes through the tissues of the head. During this time, then, we must assume that the balance of secretion over destruction is turned in favour of the former. It will have been observed that in those experiments in which the pituitary was removed before switching the head into the circuit there was a small inhibition in the rate of urine flow and a small augmentation in the chloride output (see Fig. 4). This was a transitory phenomenon, however, and the reappearance and augmentation of the polyuria and chloride fall in the time during which the blood was still shunted through the head showed that, even if pituitrin were being continuously secreted during this time by the remaining fragments which inevitably escaped removal, its rate of destruction in the blood and tissues was certainly greater than its rate of formation.

There can be no doubt, then, that the copious flow of dilute urine produced by the isolated kidney is due to the fact that the pituitary gland is excluded from the circulation. And the experiments which have just been described have in addition an obvious bearing on the much debated question of the ætiology of diabetes insipidus.

Diabetes Insipidus.

In 1912 Frank [10] drew attention to the association between lesions in the neighbourhood of the hypophysis and diabetes insipidus, and in the following year von den Velden [22] demonstrated that the polyuria of this disease could be completely controlled by the subcutaneous injections of an extract of the pituitary body. Since that time two main views have been held on the ætiology of this disease, each having its adherents both on the clinical and experimental side. According to the one view the polyuria is due to a disturbance of the hypothalamus, leading to a failure of this part of the brain to regulate the output of water and chloride by the kidneys. According to the other view the polyuria is due to interference, either as the result of disease or as the result of experimental intervention, with the functions of the pituitary body. The occurrence of polyuria following the experimental removal of the pituitary body in mammals was reported by several investigators before the work of Frank [10] and of von den Velden [22] was published. Vassale and Sacchi [18] in 1892 noted this sign in some of their experiments and recorded the low specific gravity of the urine. Gemelli [11] also observed it frequently during the first five to six days following "total" ablation of the hypophysis.

Fig. 5.



The control of experimental diabetes insipidus in the dog by intravenous infusion of pituitrin. At A pituitary body removed. At B infusion of "Infundin" (2 per cent.) commenced, and finished at C. H, Urine flow right kidney in c.cm. per 15 min., and G, that of left kidney. E, Chloride of urine from right kidney, and D, that from left in mg. per cent. as NaCl.

Crowe, Cushing, and Homans [6] state that following total hypophysectomy in adult dogs the urinary output diminishes to anuria, but that in puppies a transient polyuria is often observed.

Since Frank's paper appeared many investigations have been undertaken with the expressed object of determining more accurately the relation between disturbance in the hypothalamic region and diabetes insipidus. On the experimental side we have the evidence of Camus and Roussy [3] that the polyuria is due, not to ablation of the hypophysis, but to a superficial lesion of the base of the brain in the optopeduncular space. This experience is acquiesced in by Houssay,[13] Leschke,[15] and by Bailey and Bremer.[1] Indeed, Camus and Roussy, and Leschke are agreed that extirpation of the whole hypothesis does not produce polyuria if the brain base is avoided. On the clinical side Leschke [15] has collected many cases in which destruction of the whole hypophysis by tumours, syphilitic and tuberculous disease, and by cisticercus cellulosæ have not been accompanied by diabetes insipidus, whilst pathological processes involving the brain base in the optopeduncular region have been so accompanied. Further, the clinical observation that thirst precedes the onset of the polyuria is often advanced as an argument against the hypophyseal ætiology of the disease.

On the other hand, we have the presence in this region of a body from which an extract can easily be prepared which inhibits in the vast majority of cases the diuresis of diabetes insipidus, whether clinical or experimental. Camus and Roussy,[4] however, state that the immediate polyuria following a lesion in the optopeduncular space in dogs is not controlled by pituitary extract, and that in experimental

polyuria of permanent duration the results of opotherapy are inconstant, without lasting effect, and, when positive, not specifically due to pituitary extract.

Before attempting to correlate the evidence which is at present available in connexion with the ætiology of diabetes insipidus, into a theory which does not run counter to the facts of observation and experiment, I should like to put before you the results of some experiments, 33 in number, which I have performed during the last few years to determine the acute effects of removal of the pituitary body in dogs.[20] All the animals were anæsthetised with chloralose. Some were give a preliminary injection of morphia, others not. To some tap-water was given by stomach-tube in doses ranging between 25 and 40 c.cm. per kg. body-weight, to others no water was administered. In some cases the left kidney was denervated after exposing it in the lumbar region, in other cases the kidneys were not interfered with. In all the experiments each ureter was exposed, by extraperitoneal dissection in the flank, and a cannula tied into position. The pituitary body was then exposed through the temporal route, and a continuous record of the arterial blood pressure obtained. About half an hour later, by which time sufficient urine had been collected for purposes of analysis, the pituitary body was removed. The preliminary exposure allowed its removal with rapidity and ease, and no change in the arterial blood pressure was detectable. Urine samples were then collected till the experiment was brought to a close. Serial sections of the infundibular region of the brain and of the pieces of pituitary tissue which were removed during the experiment, were made. The kidneys were also sectioned with the primary intention of determining whether any fibrosis was present. In 18 of the experiments a well-marked polyuria, varying in different experiments between 4 and 24 times the original rate of urine flow, became manifest. In seven of the experiments there was only a slight increase in urine flow following removal of the pituitary body, and in the remaining eight experiments no increase was detectable.

The results of an experiment in which polyuria appeared to a marked degree are plotted in Fig. 5. It will be seen from this experiment that removal of the pituitary body was followed after a latent period of 30 minutes by an increase in the water output of both kidneys and by a fall in the percentage of chloride in the urine. When the polyuria had reached its maximum figure a slow intravenous infusion of pituitary extract was begun with the object of determining whether this polyuria could be inhibited by this means. It will be seen from the figure that the kidney responds immediately to this infusion by a diminution in the water output and a percentile rise in the excretion of chloride. By carefully regulating the rate of infusion it was possible to maintain the rate of urine flow at approximately its original level. When this was done it was found that the chloride content of the urine had also returned approximately to its original value. The continuous infusion of pituitrin therefore had brought the kidney back to a physiological state indistinguishable from that which it exhibited before its experimental divorce from the pituitary body. This infusion was stopped at C, and after a short latent period, 15 minutes, the increase in urine flow and fall in urinary chloride again projected into the picture. In eight experiments of this type the mean of the rates of infusion which were found necessary to inhibit the polyuria completely was a fiftieth of an international unit per kilo per hour, the extremes being one-hundredth and one-thirtieth of a unit. No experiments have so far been performed to determine whether the oxytocic or pressor factor is responsible for the control of a polyuria brought about in the manner described. It is of interest to know that no change in the concentration of hæmoglobin in the blood accompanies the polyuria. The water therefore passes from the tissues to be excreted by the kidney without producing any obvious signs of its transit.

In those experiments in which polyuria appeared, there was a latent period varying from 25 to 60 minutes between the time of removal of the pituitary body and the time at which the first signs of an increase in urine flow appeared, a delay which is clearly to be attributed to the gradual disappearance of the antidiuretic hormone from the blood stream after its seat of production had been removed. The polyuria was found to be more profuse on the left side in those cases in which the sympathetic nerves to the left kidney had been divided.

The experiments which have just been described would lend strong support to the view that diabetes insipidus is due solely and directly to the lack of the pituitary antidiuretic hormone in the blood were it not for the fact that in 25 per cent. of the cases, as previously stated, the polyuria did not appear. It has not been found possible to correlate this failure of response with the presence or absence of any of those factors which varied or were varied, during the conduction of this series of experiments—namely, the preliminary injection of morphia, the administration of water by the mouth, the sex of the animal, the amount of pituitary tissue which escaped removal, or the degree of injury to the infundibular region of the brain. Neither was the absence of response due to fibrosis of the kidney.

In view of these facts, and of the evidence brought forward by other investigators against the hypophyseal ætiology of diabetes insipidus, it becomes necessary to examine this evidence more closely before discarding a theory to the validity of which so many facts bear testimony. This evidence may be stated briefly as follows:—

1. Extirpation of the whole hypophysis does not produce polyuria if the brain base is avoided. (Camus and Roussy; Leschke.)

2. Polyuria is produced by a superficial lesion of the base of the brain in the optopeduncular space. (Camus and Roussy; Leschke; Houssay; Bailey and Bremer.)

3. Pathological destruction of the whole hypophysis in man is not necessarily followed by diabetes insipidus. (Leschke.)

4. Pathological processes involving the base of the brain in the optopeduncular space are often accompanied by diabetes insipidus. (Leschke.)

5. Thirst often precedes the polyuria.

6. Surgical removal of the pituitary body is not invariably followed by diabetes insipidus. (Verney.)

A study of serial sections of the infundibular region after removal of the pituitary body demonstrates quite clearly the intimacy of the association between the pars tuberalis and the base of the brain. The association is so close that complete experimental removal is impossible without extensive injury to the nerve structures in the floor of the third ventricle. And a considerable body of evidence exists that such complete removal is incompatible with the survival of the animal. Further, destruction of the pituitary body by disease must be shown by serial sections to be complete, before absence of polyuria in such conditions can be brought forward as unequivocal evidence against the part played by the hypophysis in producing diabetes insipidus. And this has not been done. On the other hand, the non-appearance of the polyuria when the pituitary body is only partially removed is clearly not evidence against the polyuria, when it appears, being due to deficiency in the secretion of pituitrin. Further, it may be pointed out that a polyuria resulting from injury to, or disease in, the hypothalamic region does not preclude the possibility of the hypophysis being concerned in its production. Nor can the impotence of pituitrin to inhibit the polyuria in certain cases be accepted as evidence against the hypophyseal ætiology of the condition, unless the activity of the preparation is concurrently controlled by the production of positive

results in other cases. Again, the fact that the sensation of thirst sometimes precedes the onset of polyuria is clearly not irreconcilable with the view that the polyuria itself is due immediately to an inhibition of the activity of the pituitary body in so far as the secretion of the antidiuretic principle is concerned.

We may conclude that no evidence of an incontrovertible nature exists at the present time against the view that the polyuria of diabetes insipidus is due immediately to an inhibition or arrest of the secretion of an antidiuretic principle by the pituitary body, and that there exists a strong body of evidence in its favour.

We may now consider for a moment those experiments of the series to which reference has already been made, in which subtotal removal of the pituitary body was not followed by a copious flow of urine. It may be that the remaining fragments of pituitary tissue were still secreting a quantity of the antidiuretic hormone sufficiently great to prevent the appearance of the polyuria. On the other hand, it may be that in these cases the kidney itself failed to respond to the withdrawal of the hold which the pituitary hormone was previously exerting. We must remember that the incidence of the polyuria in all probability demands an increase in the work done by the kidney, and it has been shown in the case of the isolated kidney of the dog, that the inhibition of the polyuria of this preparation by pituitrin is accompanied by a fall in the oxygen consumption of the kidney (Fee and Hemingway [9]). It may well be that the kidney must be in a reactive state—in a condition of good "tone"—before it can respond to the removal of the inhibitory influence of pituitrin. The reins may be slackened, but the horse does not of necessity increase its pace. This conception of the condition of the kidney itself contributing to the degree of its diuretic response, gains in plausibility when it is pointed out that in my own series of cases it was observed that this response to the removal of the pituitary body was much more likely to occur in the case of young and lively dogs than of those older in years or more phlegmatic in temperament. And in man diabetes insipidus is a disease affecting young people. Further, as we shall see in the next lecture, a diminution in the reserves of the isolated kidney leads to a diminution in the antidiuretic response to a given concentration of pituitrin in the blood. It is evident, then, that the condition of the kidney itself is to be regarded as an important factor in determining whether, and if so to what degree, it will respond to a diminution in the secretion of the pituitary body.

The symptom of thirst, which may be the initial complaint in diabetes insipidus in man, leads us to a consideration of the mechanism involved in the response by the kidney to the intake of large volumes of water by the mouth.

Polyuria Following Water Ingestion.

If a large volume of water be drunk by a healthy man a great increase in urine flow soon becomes evident, and the volume of water ingested is rapidly and quantitatively excreted. 2000 c.cm. of warm tap-water swallowed in 12 minutes by one man were completely eliminated within four hours, the maximum rate of flow, 12 c.cm. per minute, being reached about 50 minutes after the beginning of the ingestion. An increase from the resting level of excretion was detectable within 20 minutes. In the case of another healthy man the ingestion of 2500 c.cm. of warm tap-water in 15 minutes was followed by an increase in urine flow, detectable within 30 minutes of the beginning of the experiment, and mounting rapidly to reach the high rate of 22 c.cm. per minute 70 minutes after the beginning of the experiment. In this case the volume of water drunk was quantitatively eliminated within three hours. There is thus considerable variation among normal men in the type of curve obtained by plotting rate of water elimination against time. In some the curve is flattened and somewhat protracted, in others higher and less prolonged.

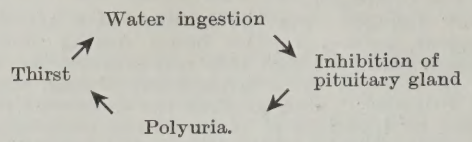
Any changes from the normal, of a physical or chemical nature, in the blood during this large diuresis, and to which this response by the kidney can be referred are conspicuously absent. Haldane and Priestley [12] showed that the enormous diuresis caused by ingestion of water was not dependent on the general dilution of the blood, although Priestley [16] was able to detect a small diminution in the electrical conductivity of the serum under these conditions. Further, no change is detectable in the osmotic pressure of the plasma proteins at the height of the diuresis from its value immediately before the ingestion of the water.[20] If, on the other hand, water or hypotonic saline be slowly injected intravenously into the dog a diminution rather than an increase in the rate of urine flow occurs.

What, then, in the absence of any blood changes which might be regarded as sufficient in themselves to evoke so gross a diuresis, is the stimulus to the kidney causing it to react in so perfect a manner by secreting a copious urine of extremely low specific gravity? The whole experimental investigation of the question is surmounted by the difficulty that water diuresis cannot be produced in animals when under the influence of an anæsthetic. When water (30 to 40 c.cm. per kg. body-weight) is introduced into the stomach of a dog under chloralose anæsthesia this water is rapidly absorbed from the gut, and its passage into the tissues is proved by the fact that no variation in the concentration of hæmoglobin in the blood occurs during this absorption.[20] But the water fails to pass from the tissues to be excreted by the kidney.

We have already seen that subtotal removal of the pituitary body in dogs is followed in favourable circumstances and after a latent period of 30 to 60 minutes by a profuse flow of urine of low specific gravity, and that the water is transported from tissues to kidney without there being detected any changes in the state or composition of the blood. Is it possible that when water is ingested by man or is introduced into the stomach of an unanæsthetised dog the increased load of water in the tissues, following its absorption, produces, through the intermediation either of a chemical messenger or of the nerve channels subserving the sensation of thirst, a temporary inhibition of the secretion by the pituitary body of the antidiuretic hormone, and the consequential excretion by the kidney of a copious and dilute urine? The only direct piece of evidence in favour of this hypothesis is the fact that, as Priestley[16] showed, water diuresis in man can be completely inhibited and delayed for a period of four to six hours by the intramuscular injection of small amounts of an extract of the pituitary gland. But when to this piece of direct evidence we add evidence of a more indirect character obtained from a comparison of the course, nature and responses of the diuresis following water ingestion with those of the polyuria of the isolated kidney and of experimental diabetes insipidus, conviction as to the truth of this hypothesis gradually gains ground. In all three conditions the character of the urine is the same, and in all there is a latent period of approximately the same duration between the laying down of the primary stimulus, be it isolation of the kidney, removal of the pituitary body, or the ingestion of water, and the diuretic response by the kidney. All react in precisely the same manner to the administration of an extract of the pituitary body, and both in diabetes insipidus and in water diuresis the doses of extract required to produce inhibition of urine flow are of the same order of magnitude. Again, in none of the three conditions has any change in the composition of the blood, to which the diuresis might be ascribed, been detected.

Perhaps the thesis of this lecture, in so far as it is an attempt to show the common part played by the pituitary body in the disturbances of urine secretion

which we have been considering, may be summarised in diagrammatic form as follows :—



The polyuria following isolation of the mammalian kidney is due to the removal of this organ from the normally sustained antidiuretic action of the secretion of the pituitary body. Diabetes insipidus is due to the divorce of the pituitary body from the kidney, whilst water ingestion in all probability leads to a temporary inhibition in the function of the pituitary, and so to the release of the kidney from its antidiuretic influence ; though the mechanism by which such a physiological inhibition is produced is, at the present time, by no means clear.

It is fascinating to think that the kidney, during the appearance and disappearance of the polyuria which we have been considering, may be recapitulating in the course of a few hours a retreat towards and an advance from the state in which our kidneys functioned in those far-back days when, eft-like, we crawled from the water to pursue our phylogenetic development on land.

THE USE OF AVERTIN FOR ANÆSTHESIA.

BY JOSEPH BLOMFIELD, M.D. CAMB.,
SENIOR ANÆSTHETIST TO ST. GEORGE'S HOSPITAL;
AND
F. E. SHIPWAY, M.D. CAMB.,
SENIOR ANÆSTHETIST TO GUY'S HOSPITAL.

AVERTIN was first made by R. Willstätter and W. Duisberg in 1926 and introduced into practice by Prof. F. Eichholz. Later he requested Dr. H. H. Dale to further the trial of it by English anæsthetists, and the matter was brought before the Anæsthetics Committee set up by the Medical Research Council and the Section of Anæsthetics of the Royal Society of Medicine. Through this committee, of which we are both members, we have been enabled to obtain supplies of the drug, which is not yet on the market in the ordinary way, from Bayer Products Ltd., and to facilitate the supply to others who wished to try it. These investigators, Basil Hughes, F. J. Morrin, and F. P. de Caux, have kindly sent us their reports. The substance of these is incorporated in this paper, which we are publishing at the request of the Anæsthetics Committee.

Chemical and Physical Properties of Avertin.

Avertin is tribromethyl alcohol (CBr_3CH_2OH), a white crystalline powder soluble with difficulty in water at body temperature to the extent of 3·5 per cent. In making the solution prolonged shaking is needed to avoid the formation of lumps. For anæsthetic purposes it is used per rectum. It has a slightly brackish taste and smell. The solution is unstable and therefore must be prepared shortly before use. If it decomposes dibromacetaldehyde is formed, which is highly irritating to the intestinal mucous membrane. In order to be sure of the purity of the solution it is tested immediately before use by adding two drops of 1–1000 Congo red to 5 c.cm. of the solution. No blue coloration must be produced.

Obviously the preparation of a solution which required such considerable time and care—taking as a rule about three quarters of an hour—was a practical disadvantage to the use of avertin. This has been got over by the makers, who now provide a fluid avertin, a liquid in which the solution of avertin is kept stable by the presence of amylene hydrate. All our earlier cases were conducted with solutions made from the powder, all the later with the fluid avertin. We find little difference in the behaviour of the two as regards their anæsthetic nature, but the fluid preparation seems more effective and less likely to be attended by respiratory depression. The "fluid avertin" provides one gramme of avertin in each cubic centimetre of the liquid. The solution for injection is made by adding distilled water at 40° C. The two must be well shaken or avertin is apt to crystallise out, but the preparation of the necessary amount and testing is now only a matter of a few minutes. Although "fluid avertin" is itself stable, strict care is still necessary in preparing the solution with distilled water for rectal injection. The proper heat 38°–40° C. must not be exceeded, and the Congo red test must be applied before injection. We have carefully investigated the stability of the solution for injection and find that it remains undecomposed for at least 48 hours at ordinary room temperature.

H. Gainsborough and J. A. Gardner kept a solution of solid avertin, 3 per cent. strength, made in distilled water at 32° C. at ordinary room temperature for 14 days. At the end of that time it was still neutral to Congo red. The solution was then raised to boiling-point, after which it showed acidity to the same test. Liquid avertin under the same conditions showed no decomposition at the end of five days. Some of the solution was then placed in a quartz vessel and exposed for 12 minutes to the light of an iron arc, after which it showed the presence of a trace of mineral acid.

The practical deduction from the above investigations is that if the solution of fluid avertin prepared for injection is kept at a temperature of about 32°–38° C. and not exposed to light it may be used even several days after preparation. The results referred to are confirmed by some experiments carried out at Guy's by E. Williamson.

If allowed to cool avertin crystallises out and, of course, if the solution is heated much above 40° C. decomposition readily takes place. The hydrobromic acid thus formed is at once detected by the Congo test, and we believe in practice that the use of this simple test of the solution just before injection completely prevents any danger from the use of an impure liquid.

In no patient of our series have we had any evidence of local damage or irritation to the bowel from the injection, an important consideration with all rectal anæsthetics. The use of paraldehyde, for example, has been by no means equally free from accidental damage to the lining of the bowel.

Results of Administration.

Although the number of cases (198) on which this account is based is not great, yet we think that they are enough to provide a sound basis for estimating the true value of avertin. For the patients have been subjects of a wide range of operations, from simple measures such as ligature of piles to laryngectomy, gastrostomy for carcinoma, hysterectomy, and thyroidectomy for exophthalmic goitre, and we have purposely chosen not only typical examples of healthy persons at various stages of life, but also those who were essentially poor subjects for operation and anæsthetics. The two fatalities which we met were both in subject

of the latter class. In one we consider that avertin can be wholly exonerated. In the other it is probable that it played a part, but just how important a part is by no means clear. As, however, in the early days of a new anæsthetic all cases are important which tell against it at all we give details of these two.

The first of these two patients was a woman aged 26, the mother of one child, suffering from a severe degree of mitral stenosis and aortic regurgitation. She was dyspnœic and cyanosed. Her weight was 9 st. 2 lb. She was seven months' pregnant and after a consultation it was decided that the pregnancy must be terminated and that at the same time, with a view to future safety, the patient should be sterilised. A subtotal hysterectomy was decided on as the best measure. The patient's condition as to circulation and respiration made it appear highly improbable that she could survive any inhalation anæsthetic. The choice was held to lie between a spinal injection and avertin. The latter was chosen and a dose of 5·8 g. in 200 c.cm. distilled water was administered at 10.35 A.M., after gr. 1/3 omnoform half an hour previously. At 11.5, when moved to the operating theatre, the patient was muttering and not fully unconscious. Ten drops of chloroform-ether mixture were given from an open mask. The further progress of the case is indicated by the following notes :—

11.14 A.M. : Corneal reflex still brisk and the dose of C.E. repeated.
11.15 : Slight movement of legs on cleaning up abdominal skin ; no further anæsthetic given.
11.17 : Skin incision—a slight movement of legs. Patient slightly cyanosed.
11.19 : Uterus delivered.
11.20 : Tubes clamped.
11.22 : Oxygen administered.
11.24 : Colour improved. Pulse 112, strong.
11.26 : Uterus removed.
11.30 : Corneal reflex perceptible ; pupils small.
11.51 : Peritoneum being closed ; corneal reflex brisk ; slight movement left hand.
12.8 P.M. : Operation completed. Pulse 129 ; respiration-rate 34 ; colour fairly good. Surgeon regarded anæsthesia during operation as perfectly satisfactory.
12.20 : Patient back in bed.
1.10 : Patient conscious ; condition fairly good, but many moist sounds in chest.
3 : Condition not so good. Much coughing of frothy fluid and pulse very rapid. Hypodermic of atropine, gr. 1/50.
3.20 : Pulse 140, respiration-rate 36. Cyanosis ; oxygen given for ten minutes.
3.45 : Patient gradually became unconscious ; caffeine injected. Died at 4.15 P.M.

Post-mortem examination showed aortic incompetence, the aortic cusps being thick and incompetent, mitral stenosis of a high degree, and lungs with much œdema but no consolidation.

The other case was of quite different type. The patient was a coster, aged 54, weighing 12 st. 11 lb., complaining of a large tumour of the neck and hoarseness. The diagnosis was a large cystic adenoma of the thyroid with compression of the trachea. The patient was thickly built, with highly coloured face, short neck, and fat abdomen—obviously a difficult subject for anæsthetics. It was thought that the use of avertin by abolishing or greatly diminishing the inhalation anæsthetic would be of great service. He was given omnoform, gr. 2/3, at 12.30 P.M. and avertin at 1.50. The dose injected was 8·57 g. in 250 c.cm. of water at 40° C. (i.e., 0·125 g. per kg. of body-weight). It was noticed that the omnoform had produced no drowsiness at the time of giving the avertin. Unconsciousness was produced without any excitement and at 2.10 the corneal reflex was gone.

The operation was begun at 2.30. The skin-cut produced very slight reflex and no general anæsthetic was administered. By 3 o'clock the cyst was completely freed and the patient's stertor ceased. There was considerable trouble with bleeding before the operation was finished at 3.20. When the dressings were about to be applied it was seen that some bleeding into the wound was still going on, so the stitches were removed, the wound reopened, and the bleeding satisfactorily dealt with. At 3.35 the skin was sewn up and dressings put on. The man's condition throughout had been good and no anxiety had been caused by the hæmorrhage. Anæsthesia was all that could be desired. The subsequent notes supplied by the house surgeon were as follows :—

6.30 P.M. : Corneal reflex not returned, pupils contracted. Pulse 120 ; tends to be irregular. Respirations not deep, but quite regular. No cyanosis. Rectal salines administered.
12 midnight : Slight corneal reflex. Pupils still small. Pulse and colour good. Does not reply to questions.
6 A.M. : Breathing not so good. Pulse poor in volume. Stimulants ordered.
9.30 A.M. Heart failure. Respirations shallow, but regular up to the time of the pulse failing. Artificial respiration and strychnine did not have effect.

The facts of this case suggest that a perfect anæsthesia on the table was procured at the price of an overdose. The dosage of avertin employed (0·125 per kg.) has often been exceeded with safety, but it is possible that in conjunction with the effect of omnoform, gr. 2/3, it was excessive. On the other hand, the patient was a bad type of subject, and it is possible that his heart would have given out after the operation even had this been performed with an ordinary inhalation anæsthetic, or with an intratracheal administration.

Premedication and Administration.

The German workers almost without exception gave their patients a dose of veronal or some similar drug on the evening before operation. We have consistently omitted this, and have not found any reason for adding the extra sedative. We have used as a routine either morphia-atropine or morphia-scopolamine (F. E. S.), or else omnopon alone (J. B.), given one and a half to one hour before operation. Our experience is that these hypodermic injections enable a weaker dose of avertin to be effective than that which can be successful without their aid. The rectum should be washed out the evening before operation, and it is important not to have this repeated within a few hours of giving the avertin.

We have found that with the ordinary routine preparation of patients for operation, and a rectal wash out with simple water on the evening before the day of operation, conditions have been perfectly satisfactory for the use of avertin any time between 9 A.M. and 1 P.M. on that day. The patient lies in bed on the left side and the avertin solution at a temperature between 35° and 40° C. is slowly run in from a funnel through a small calibre soft rubber tube or catheter. This should be vaselined and passed at least four inches beyond the anus. Not less than ten minutes should be spent in introducing the solution. After it is all in, the tube may be clamped and left in position, or withdrawn and a tampon of cotton-wool with boric ointment applied. It is a great advantage if the anæsthetist can himself be present when the injection, which is entrusted to a nurse, is carried out. He may be able, by noticing the onset of unconsciousness and the general reaction of the patient, to reduce the prescribed dose, as we have several times done, or, on the other hand, he may realise the necessity for additional anæsthetic later. In any case the person entrusted with the injection must be sufficiently skilled to be safely entrusted with a deeply unconscious patient. She must know how to prevent mechanical obstruction of the upper air passages, for the tongue is easily drawn back with inspiration so as to obstruct the larynx, in the patient fully under avertin, just as it is in the case of inhalation anæsthetics. There is, however, none of the local congestion associated with inhalation anæsthetics and consequently the airway is more easily preserved.

Dosage.

The dose used has been between 0·09 and 0·15 g. per kg. of the patient's body-weight, given in a 3 per cent. solution with distilled water. One of us (J. B.) has used, except in his first few cases, nothing but the dose of 0·1 g. per kg. always preceded by gr. 1/3 of omnopon. All the evidence so far secured shows this to be a safe procedure. On the other hand, the anæsthesia obtained is, of course, often inadequate

and has to be supplemented, usually by a little ether. One-third of the cases required no anæsthetic in addition to the avertin. By stronger doses of avertin, 0·13 g. and 0·15 g. per kg., the necessity for additional anæsthetic arises less often (F. E. S.).

The question of the correct dose is the most difficult one in connexion with avertin, as indeed with any rectal anæsthetic. If only a perfectly safe amount is injected this will often be inadequate and will have to be helped out by inhalation or by local analgesics, the method favoured by Mr. Basil Hughes. If, on the other hand, maximum doses are employed, although the anæsthesia will much more often be adequate without any supplementary method, yet the risk of overdose must necessarily be great. For gauging the dose by the body-weight is, after all, only a rough guide, and we all know the varied way in which different patients react to narcotic drugs, although the reason for the difference in their behaviour is generally obscure. Consequently we believe that the former of the two methods mentioned should be followed and that avertin should be used to provide the induction of narcosis and an excellent basis on which with comparatively little inhalation a perfectly satisfactory anæsthesia can be established.

Another safe method that has been much practised by some German surgeons meets with the approval of Mr. Morrin, who has used it with success. This is what is called fractional administration. A dose is first given equivalent to 0·1 g. per kg. of body-weight. If after 15 minutes the patient is sensitive to pain a further dose of 0·025 g. per kg. is given, and this is repeated if necessary till the maximum of 0·15 g. per kg. has been injected. This method requires that the rectal tube is kept in position and, of course, there may be some inconvenience in continuing the injection on the operating table. We have preferred the method of reinforcing the narcosis of avertin when necessary by inhalation anæsthesia. Sometimes gas and oxygen has been used, but most often a small amount of open ether or of C.E. mixture.

Effects of the Injection.

Avertin is rapidly absorbed from the bowel. Symptoms are generally produced within a few minutes, and we are satisfied that the whole amount introduced does actually leave the bowel, because we have in many patients had the bowel washed out after return to bed and the wash-out carefully examined for avertin. None has ever been discovered. Morrin has recovered some fluid when the bowel has been washed out within 40 minutes of the injection. We have never washed out as soon as this, believing that it takes about 45 minutes for the whole injection to be absorbed. Consequently we do not think there is any advantage in leaving the rectal tube in situ for the purpose of withdrawing avertin solution should symptoms of overdose appear in long operations.

Avertin produces unconsciousness more quickly and quietly than any similar drug with which we have had experience. We have seen no example of excitement nor any evidence of unpleasant taste or other sensation. The usual process is that after a few minutes the patient's eyes close and he responds languidly to questions; usually within 15 minutes he does not answer at all. If his eye reflexes are now tested the conjunctival is quite absent and the corneal usually so, too. The pupil is very small, but reacts to light. The general musculature appears relaxed. Respiration is quiet and regular, often with stertor from the relaxed jaw and tongue, and the pulse is in accordance with the breathing. There is slight fall in blood pressure, usually about 10 mm. Hg. It is greater in proportion as the strength of the dose is increased. The colour remains normal if due care is paid to the airway. If the patient is now, some half hour after his injection, placed on the operating table his appearance suggests that he is fully anæsthetic. The application of iodine or picric acid and of the towel clips will, however, often elicit slight reflex movements, and then a small amount of general anæsthetic had better be at once given before incision. The amount required will be quite small (e.g., 2 drachms of ether on an open mask) and may not have to be repeated. On the other hand, we have had to use as much as 7½ oz. of ether.

Another test for the real depth of narcosis which has been found useful is to apply an open mask, well wetted with ether, close to the face. If there is no alteration in the breathing, from irritation of the larynx, the operation can be begun without fear of any inconvenient movement on the patient's part.

In the course of operation we have found no untoward effects of avertin on the respiration or circulation. The breathing goes on quietly and regularly. The blood pressure has never fallen more than 30 mm. Hg unless the severity of the operation itself produced a fall. We have never had to apply any kind of restorative measures on the table. Apparently those most likely to be required are direct respiratory stimulants (lobeline or CO_2) or else ephedrine to restore blood pressure. The above description of the effects of avertin is true of the vast majority of cases. The exceptions have been provided by alcoholic subjects. In these nothing more than a stupefying effect may be obtained, with an associated amnesic effect, so that next day, although a large amount of general anæsthetic has been given, the patient remembers nothing after the rectal injection.

Recovery Period.

The patient remains unconscious generally for about three hours after return to bed. During this time, however, the corneal reflex is brisk and the sleep is light, so that probably it could be broken if necessary by any violent stimulation. The importance of this is that during this period foreign matter probably could not enter the larynx without being ejected, and we do not think that avertin need be avoided in operations which involve the air passages for fear of inhalation of blood afterwards. For these cases, however, it would probably be safer to omit all preliminary sedative medication.

Mr. Morrin's operations, a large proportion of which were diathermic coagulation for extensive carcinoma of tongue or tonsil, bear favourably on this point.[1] His remarks may be quoted that "avertin anæsthesia, by allowing accessibility to the growth and free intra-oral manipulation, marks a great advance in the operative treatment of lingual and oral carcinoma."

The after-effect of avertin is really more a prolonged period of analgesia and amnesia than a true unconsciousness, and this long period of freedom from pain is often an advantage. Chest complications have been absent, as was expected, since elimination of avertin does not take place through the lungs. It is got rid of by way of the liver and kidneys in combination with glycuronic acid. Assuming that it appears in the urine as a glycuronate, in four or five cases Gainsborough and Gardner made daily analyses of the urine for two to four days and accounted for from 20 per cent. to 64 per cent. of the avertin administered. They concluded, however, that the methods of estimation were unreliable and required further investigation. German observers have found as much as 80 per cent. Attempts were made to determine the amount of avertin in the blood, based on the quantity of combined halogens, but the differences were so small as to be within the errors of experiment.

After-effects have been noticeably absent. There has been no affection of the lungs when avertin only has been used, nor indeed, with slight exceptions, in the other cases which had supplementary anæsthetics. One of these patients (de Caux), after a gastro-enterostomy carried out with avertin and gas and oxygen, developed purulent bronchitis from which he recovered. This man had 0·125 g. per kg. and remained cyanosed for nine hours after operation and was still drowsy after 24 hours. Nausea and vomiting in the great majority of cases have been absent.

[1] See THE LANCET, March 2nd, p. 448.

Conclusions.

There appears to be no contra-indication to the use of avertin on the score of age. Basil Hughes speaks enthusiastically of its use for children, combined with infiltration anæsthesia, and some of our own most satisfactory experiences have been with aged persons. Nor does any state of bodily health, except rectal disease, apparently forbid its use. Cachectic, feeble persons suffering from carcinoma of the œsophagus have undergone gastrostomy under avertin anæsthesia with complete success, and the same result attended an operation for gall-stones in the jaundiced subject. Nevertheless we would not use the drug if the liver or kidneys were known to be seriously diseased.

We believe that its use has especial value: (1) for patients who dread the anæsthetic, or have suffered after former anæsthetics; (2) for the subjects of exophthalmic goitre, or others in whom the psychic aspect of the matter is of real import; (3) for patients who have to undergo long operations not requiring very deep anæsthesia—e.g., long operations on bones, plastic operations, laryngectomies; (4) for injections for trigeminal neuralgia; (5) for patients who suffer from any pulmonary complaint; and (6) in prolonged operations about the head and neck. We do not think avertin, being administered by a single dose method, should be used for operations likely to cause rapid fall of blood pressure.

We consider avertin to be a valuable addition to the drugs at the disposal of the anæsthetist, and that if used with due care and moderation its advantages can be taken advantage of with perfect safety.

We wish to acknowledge the assistance of members of surgical staffs of Guy's and St. George's who have kindly allowed us to use avertin for operation cases; and also the valuable help given to one of us by Mr. G. Edwards and Mr. L. N. Lewis, resident anæsthetists at St. George's.

AIR-TIGHT SUCTION DRAINAGE OF THE CHEST.

By HAROLD BURROWS, C.B.E., F.R.C.S. Eng.,
CONSULTING SURGEON TO GOSPORT HOSPITAL.

Resection of a piece of rib for the purpose of draining the chest has been a life-saving operation, and the procedure may be regarded as a milestone on the road of thoracic surgery. Nevertheless this method will not save every patient who has an empyema, and in certain conditions the mortality which follows open drainage of the chest is too high to be regarded with complacency. For example, in very young and in old sufferers open drainage is not a satisfactory therapeutic measure, and it falls short in the cure of infective pleurisy associated with pneumonia or other grave concomitant lesion, and in the acute septic effusions which are not bounded by pleural adhesion prior to the opening of the chest. The mortality which attends rib resection in these cases, and the complications which are apt to follow, have received full recognition, and many attempts have been made to elude the drawbacks by effecting some form of drainage which would allow the egress of septic fluid from the chest while preventing the ingress of air to the pleural cavity. For the most part these endeavours have not been successful, but a real step forward was made by Poynton and Reynolds,[1] who, under the title of a Method for Diminishing Mortality in Empyema in Infancy and Childhood, introduced a technique which they had devised with the special object of emptying the pleural cavity and maintaining continuous drainage by aspiration without at any time exposing the cavity to the outside air and secondary infection. Poynton and Reynolds use a special trocar and cannula. The latter is fitted with a broad flange which fits against the chest wall, and suction drainage is effected by means of a rubber tube which fits the cannula tightly, having been passed through it while on the stretch, like a self-retaining catheter, and which is connected up with a White's continuous suction apparatus (Fig. 1). The object of the present communication is to propagate the views and method of Poynton and Reynolds, to advocate their application to the treatment of empyemata in adults, and to offer a few suggestions appropriate to the practical side of the question.

[1] The Lancet, 1921, ii., 1100.

With regard to the advantages of continuous air-tight suction over rib resection in the treatment of these infected pleural effusions in children I will take the liberty of quoting freely from the original paper by Poynton and Reynolds. They mention the following:—

1. The period of illness is shortened. In cases treated by rib resection the average time before the wound is healed is six weeks; with the method described above the average time between insertion of the cannula and complete healing has been 15 days. The explanation of this advantage is that:—

2. There is no secondary infection of the pleural cavity. The rubber tube has a larger lumen than the cannula, so that, when released from the introducer, it expands and fits the cannula tightly, preventing any leakage of pus, soiling of the wound, and reinfection backwards to the pleural cavity. Another important point in the shortening of the illness is that osteomyelitis of the rib, so common after resection, does not occur.

3. No anæsthetic is required. The whole procedure can be carried out in a few minutes, causing very little disturbance and without removing the patient from bed, thus eliminating all the risks attendant upon moving a seriously ill child to the theatre and giving an anæsthetic.

4. Surgical trauma and its consequent shock are reduced to a minimum. The pain and discomfort of inserting the trocar are no more serious than exploration with a needle.

5. No daily dressing is required. Those who have seen what mental and physical suffering so many children endure for weeks after resection of rib will readily appreciate what a relief this method will be to all concerned.

6. The patient can assume any required position without fear that drainage will be interfered with.

7. The drainage is continuous and complete. Pus cannot collect in the bottom of the cavity and depend upon the position of the patient or upon expiratory efforts for its expulsion.

8. Expansion of the lung is assisted. The suction produces a negative pressure of 8 mm. Hg; this being more than the normal negative pressure of the pleural cavity, the lung tends to expand and assume its normal function more readily.

9. The removal of the pus is gradual. The continuous suction causes a steady slow outflow of pus, and it is some hours before the cavity is emptied; a displaced heart is thereby allowed to reassume its normal position quietly and gradually without the suddenness which is bound to occur if incision and drainage are employed. This fact is important when one recalls cases of syncope due to sudden withdrawal of pus and the replacement of a displaced heart.

To this long list of advantages may be added:—

10. A recovery which is complete and unclouded by any necessity for those subsequent operations for decortication of a collapsed lung and extensive resections of rib that are sometimes required in order to obliterate the septic cavity remaining after the old operation, even when it has been "successful." The patient who, by suction drainage, has surmounted the immediate danger of an empyema will be free to thank Providence whole-heartedly for his recovery—a happy lot which, as we all know, does not invariably fall to those who have undergone treatment by open drainage.

11. Lastly, and perhaps most important of all, is the avoidance by air-tight suction drainage of any spread whatever of the area of pleural sepsis. With an open operation, on the other hand, accompanied as it must be in non-localised effusions by some separation of layers of pleura previously in contact, a spread of pleural infection is unavoidable.

The Drawbacks.

1. *A delirious patient may pull out the tube.*—This happened in a patient of mine, aged 54, in whom a right-sided empyema supervened on a double pneumonia. Luckily the hole through which the tube had been removed remained air-tight. A fresh catheter was inserted into the empyema cavity at a point as remote as possible from the former puncture and an uneventful recovery ensued—uneventful, that is to say, except for a local cellulitis of the chest wall which, however, quickly subsided without causing great constitutional disturbance and without necessitating any incisions.

2. *Cellulitis of the chest wall.*—This remains the one hitherto ineradicable drawback to the method. With the precautions which will be mentioned presently I do not believe the danger to be very great, even in cases of acute hæmolytic streptococcal infection, in which it is of the utmost importance to avoid any spread of the pleural infection such as is bound to occur with open drainage. In any case, a cellulitis of the chest wall is less likely to kill the patient, and is more easily dealt with than a wide-spreading streptococcal pleurisy accompanied by collapse or contraction of the lung and by profound toxæmia.

3. *Insufficient drainage due to blockage of the tube.*—This is largely a myth used for purposes of destructive argument. The suction does sometimes fail to be effective, and this may be due (supposing the disease to be still active) to one of two causes—namely: (*a*) the drainage-tube may be obstructed by a mass of fibrin, or (*b*) the tube may be inserted at too low a level in the chest wall, in which case, as the empyema cavity diminishes in size, the dome of the diaphragm comes into contact with the chest wall and so shuts off communication between the residual pleural fluid and the rubber drainage-tube.

(*a*) Blockage by fibrin is to be dealt with in this way. The drainage-tube is secured with a clip to prevent the entrance of air, and is then detached from the suction apparatus. Then, with a glass syringe, a few ounces of warm solution of eusol (I have used diluted "Milton" for the purpose) is slowly injected into the pleural cavity, the clip on the drainage-tube having been removed for the purpose. The suction apparatus is then connected once again with the drainage-tube. If recurrent blocking occurs this treatment may be repeated.

(*b*) The more common cause of defective or intermittent drainage is contact of the diaphragm with the chest wall above the drainage-tube owing to the latter being too low down, especially if the opening happens to have been made in the mid-axillary line or in front of it. The diaphragm comes readily into contact with the chest wall as high as the sixth rib in the mid-axillary line and the eighth rib in the posterior axillary line, so that if a tube be introduced at or below these levels it must be thrust far enough into the pleural cavity to avoid the possibility of its being smothered by the diaphragm. Supposing the worst to happen, and that suction drainage cannot be established, even by trying the remedies and observing the precautions just mentioned, or by inserting the tube at a different place in the chest wall, it will still be possible to resect a rib and perform open drainage. And when the surgeon is skilled, as every modern surgeon must be, in the use of local anæsthetics, the patient will have been put to very little pain and inconvenience by the previous efforts to drain his chest.

4. *The apparatus is unwieldy and tiresome to use.* The apparatus is cumbersome, but to admit this as a factor in our choice of therapy is to place the convenience of the medical attendant before that of his patient. In practice the method is not at all tiresome—far less so than the frequent dressing of an open empyema wound. The large reservoir supplying the hydraulic pump will only need refilling once in 12 hours or thereabout—a trifling labour—that is to say, with the interrupted stream flowing properly at the rate of between 60 and 100 drops in each minute.

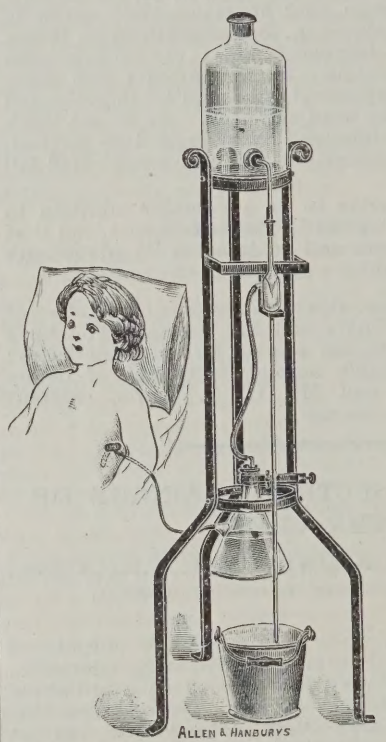
5. *The possibility of damaging the diaphragm or lung with the large trocar.*—I have feared the danger, though I have not experienced the accident. As a measure of safety I had a set of trocars made for me with truncated points, but these have the disadvantage that they will not always perforate the parietal pleura, to achieve which a narrow-handled tenotome will be necessary. Perhaps I have been unwarrantably apprehensive of this supposed danger when an ordinary trocar is used.

Alternative Procedures.

(1) It may be argued that in a case of infected pleurisy, especially when this condition is due to the pneumococcus, it will be desirable to open the chest widely in order to clear out the large masses of infected fibrin. This seems sound enough. I have suffered from repentance and remorse after an apparently successful operation of this kind, which at the time seemed most satisfactory, handfuls of clot having been found in the pleura and removed, but the death of the patient put me in the wrong. The fact is, that these large thoracotomies not only require considerable experience and skill for their performance, they not only demand as an essential the use of intratracheal anæsthesia or of a pressure chamber, but the operations are very severe on the patient, who may easily be overwhelmed by such a drastic remedy. Moreover, the test of experience will almost certainly prove that air-tight suction drainage is curative for these patients, and in the face of experience all hypothetical suppositions must be relinquished.

(2) Siphon drainage has been tried in place of active suction. That is to say, a drainage-tube is inserted into the pleural cavity through a trocar

FIG. 1.



Apparatus as used by Poynton and Reynolds. The present author differs in not using a retained cannula.

FIG. 2.

Dowse's self-retaining catheter with expanded end.

the other end of the tube being allowed to hang down over the edge of the bed into a bottle of antiseptic lotion standing on the floor. In practice, again, this alternative does not fulfil as it should the theoretical hopes which have so often been based upon it. The method is too seldom attended by success and cannot be regarded as an equivalent of, or as a substitute for, active suction, and the same drawback of ineffectiveness attends the use of valvular drainage.

When the pleura is acutely infected by hæmolytic streptococci there is but one alternative to air-tight suction drainage, and that is repeated aspiration, for it is now generally recognised that open drainage by rib resection in this type of case is a grave surgical error. Unfortunately, it is in these very infections that there is the greatest danger of cellulitis of the chest wall, and this danger accompanies both repeated aspiration and suction drainage. The actual risk from this complication, although not to be ignored, has been exaggerated; for we are not destitute of measures to deal with it.

Technique of the Operation.

Though following in the main the methods of Poynton and Reynolds, there are a few small modifications which I should like to suggest. The operation is done, of course, without moving the patient from his bed, the local anæsthetic used being 1 per cent. of novocaine in a 1 in 15,000 watery solution of adrenalin; this should be freshly prepared. A fine-bored needle is used, to minimise the danger of infecting the chest wall from within through puncture of the pleura. I prefer to enter the trocar near the posterior axillary line. The ribs are wide enough apart here to admit of the passage of a fair-sized tube, while the drainage is not so likely to become obstructed by the diaphragm as it would be if the puncture were to be made in the mid-axillary line or further forward still. For the purpose of drainage a Dowse's self-retaining catheter is chosen which is slightly larger in section than the cannula through which it is to be introduced (Fig. 2). These measurements are tested by a catheter scale so as to avoid any visual fallacy. The object of having the outside measurement of the catheter larger than that of the cannula is to ensure that there shall be no leakage of pus between the tube and the walls of the wound after the cannula has been removed. There is, of necessity, some soiling of the wound track during withdrawal of the cannula. To mitigate this, the self-retaining catheter is soaked beforehand in a 1 in 1000 aqueous solution of acriflavine, which is potent in suspending freshly initiated sepsis. After the trocar and cannula have entered the pleural cavity and before the trocar is withdrawn, a pad of cotton-wool soaked in methylated spirit is wrapped round the cannula where it is in contact with the skin, so as to prevent a surface wound infection from overflowing pus. The trocar is now withdrawn, and a finger is immediately placed over the open end of the cannula to prevent any outflow of pus. The self-retaining catheter is now quickly inserted on an introducer, and first the cannula and then the introducer are withdrawn, and as speedily as possible the catheter is connected with the suction apparatus which has already been set going. This, indeed, is almost exactly the technique used to effect suprapubic drainage of a paralysed or infected bladder, and is, I think, much superior to the plan of leaving a rigid cannula in the chest wall through which the drainage-tube is passed. The kind of self-retaining catheter selected is one in which the expanded end is in unquestionable continuity with the trunk of the catheter and is not formed from a separate piece of rubber subsequently vulcanised to the main body, for such an end might conceivably become detached and lost within the patient. Therefore a Dowse's self-retaining catheter is used; in this the continuity of the tip and body of the catheter is unbroken, and no danger of detachment of the expanded end can arise.

In view of the success which has been attained by air-tight suction drainage of empyemata and infected urinary bladders it may be well to test the method in the treatment of other acutely infected cavities—for example, in septic arthritis of the knee-joint. That, however, is a mere suggestion and is not germaine to the present article, the aim of which has been to call renewed attention to Poynton and Reynolds's suction treatment of pleural sepsis, and to add to their advice some small additional details of technique which may be of use to those who will undertake the operation.

SOME SECONDARY MENTAL STATES

AND THEIR SIGNIFICANCE.

BY R. G. WALMSLEY, M.B. LIVERP.,
ASSISTANT HONORARY PHYSICIAN, LIVERPOOL PSYCHO-THERAPEUTIC CLINIC.

THE conditions best described as "secondary mental states" are fairly common and of considerable interest. A few years ago no attempt was made to distinguish between their variations—hence the prevalence of such vague terms as "trance" and "swoon"—and the general public had a deeply rooted tendency to regard them as associated in some way with the charms and spells of witchcraft and magic. Now the pendulum of fashion has swung far in the opposite direction; everything mysterious is being put into its place according to the principles of a strict scientific determinism, and all such substates of consciousness, when they come within the province of the general physician, are labelled epileptic or migrainous, choreic or post-encephalitic, hysterical or psychasthenic according to the associated signs and symptoms and the individual predilections of the physician. Some clinicians, again, are content simply to regard these secondary mental states as toxic, or vascular, or endocrine in origin; others look upon them as the inexplicable concomitants of a potential psychosis. Nevertheless, the vast majority of them remain under the category of "functional disturbances of unknown origin," and the position is far from satisfactory.

It is essential at the outset clearly to define the conditions. They are characterised by some variation from the normal state of consciousness in which consciousness, as one usually understands that term, is retained, and in which evidence of gross mental derangement is absent. This definition therefore excludes all conditions in which consciousness is lost entirely, such as normal sleep, pathological coma, and syncope, and also those states of complete disorientation and inapperception of reality which characterise the psychoses.

Symptoms Objective and Subjective.

Observed objectively, the conditions under discussion are characterised in the slightest cases by a transient failure of attention, an apparent preoccupation, a fixed staring expression, and some immobility in the general attitude. Upon closer observation some dilatation of the pupil may be noted, together with a change in colour and some variation in the respiratory rate. Often the objective evidence of the condition is limited to a few of these signs, but in severer cases more remarkable changes can be recorded; the patient's behaviour becomes quite obviously odd, and he may show signs of perturbation and distress. The eyes may be rolled upwards, some word or expression may be muttered half audibly, the hands may be clasped in a curious wringing movement, while the respiration assumes a peculiar sighing character. In a few yet rarer instances the individual conducts himself in an entirely strange and inappropriate manner; his character appears to be altogether altered, and his affective tone and reactions to have been completely changed from those of his normal conscious state.

After a variable time he becomes himself again, and may then display a complete amnesia for the period of the change. Between those cases in which only the slightest change is observable and these extreme examples of dual personality there is a gradation of cases of all shades of intensity, demonstrating that the essential change is the same in all and that the varying symptomatology merely indicates the degree to which the process extends.

Subjectively, the symptoms are of even greater interest. Almost every apparently normal individual can recall curious phases of day-dreaming in which the thoughts revert to a more primitive phase than ideation, and in which adaptation to the conditions of external reality is less complete than at normal times. One may be expressing one's thoughts quite adequately in conversation when suddenly and without any apparent cause one loses the thread of one's argument, hesitates for the appropriate word, and is compelled to bring one's sentence to a premature conclusion; in these circumstances one usually experiences an unpleasant feeling of confusion and incompleteness. Passing from the relatively normal to the more definitely abnormal the subject describes a curious sense of unreality, a sensation as though the present situation were somehow the repetition of a similar situation in the past in which he is compelled to enact a painfully passive, automatic rôle; he may feel as though a pause had occurred momentarily in the eternal march of time, or in the rhythmic pulse of the universe, as he may fancifully express it. Objects appear to him abnormally large or abnormally small, as though viewed "through the wrong end of a telescope." A number of curious sensations, visual and auditory, visceral and cutaneous, may sometimes be elicited, and not infrequently a sense of panic, as of some awful imminence, is experienced. The whole period does not usually exceed a few minutes, and frequently its duration is measurable in seconds. In a few severe cases, however, the condition persists for several hours, but such cases are quite exceptional, and as a rule the previous tempo of life is quickly resumed, and all goes on as before. At times no subjective sensations can be elicited, but the patient may appear somewhat confused on being questioned.

Current Medical Opinions.

All these symptoms and signs are most carefully sorted out, labelled, and described under the symptomatology of a number of syndromes. In my opinion they simply indicate a substate of consciousness, and should not thus be sorted, classified, and arranged so as to form so many separate clinical pictures. They ought to be considered as a group, closely interrelated and comprising in its totality a quite definite clinical entity—in fact, a complete syndrome in its integral whole. In the text-book classifications and symptomatologies essentially the same condition—namely, some manifestation of the secondary mental state—masquerades under many names and in many guises: as the aura to grand mal, as an attack of petit mal, as an epileptic equivalent, as a post-epileptic automatism; as a visual fortification phenomenon indicative of migraine; as some form of oculo-gyric or hyperpnœic crisis suggesting encephalitis; as the cerebral manifestation of disseminated sclerosis; as the subjective symptom of vasomotor instability or of a deranged blood pressure; as one of the gamut of functional disorders ascribed to chronic toxæmia, to anaphylaxis, or to an endocrinous dyscrasia, according to the prevailing fashion; as the disturbance in movement, sensation, and memory of an hysteric; as the depersonalisation, doubts, and tics of a psychasthenic; as the light-headedness and confusion of a mild toxic psychosis; as the introspection of a neurasthenic suffering from anxiety; as the introverted phantasy of an early dementia præcox. In each case certain outstanding phenomena are extracted from the fundamental psychic state responsible for their existence, and then these phenomena, divorced, as it were, from their context and having in reality no significance per se at all, are claimed individually as important symptoms pathognomonic of many widely differing syndromes.

Failure of Cohesion in Consciousness.

Now it seems apparent that in each one of these functional disturbances for the production of which no adequate organic cause can be discovered in the vast majority of cases the essential element is fundamentally the same. True, it is interpreted rather differently by the patient according to his individual powers of observation, apperception, and self-expression; it is also tinged in each case by the local colour of any other physical symptom with which it may be associated, as, for example, headache, vomiting, or palpitation, but allowing for all these shades of variation the symptomatology really shows a remarkable degree of uniformity. My contention is that these conditions are all simply manifestations of some change in the functioning of those mental processes which combine to produce the totality of the phenomena of consciousness; they have one common and fundamentally essential character, and this is some failure of cohesion in that integration of psychophysical processes upon which the normal state of consciousness depends. In a number of cases, as in Jacksonian epilepsy and in rheumatic and lethargic encephalitis, a demonstrable pathological lesion is present, and we are justified in assuming that it bears some relationship to the symptom under discussion. The fact, however, that the same change in consciousness is found in a case of organic cerebral disease, in a case of organic non-cerebral disease, in a case of purely psychogenic disorder, and in a normal individual under very varying circumstances, proves that the relationship between the pathological lesion and the change in consciousness is entirely non-specific. In epilepsy the fallacy of regarding the symptomatology as due to some specific physical cause becomes particularly apparent; it cannot be explained in terms of structural changes, nor can subtle variations in consciousness usefully be interpreted by the light of cerebro-topography. Hence the confusion of thought regarding the pathology of such conditions as epilepsy and migraine. This consideration also offers a reason why clinical cases of these diseases so seldom conform to the classical types described in text-books. The differential diagnosis between true and false epilepsy is finally reduced to absurdity by that most assuredly psychogenic of all symptoms, involuntary micturition, the signal hall-mark of fear, clinching the diagnosis of an organic case. The whole process becomes intelligible when one adopts a psychological conception of the disorder, and realises that the primary condition in all these modifications in consciousness is some degree of dissociation, and that the actual line of the cleavage is predetermined by purely psychological factors, while any disturbance in the physiological working of the organism as a whole is able to increase this potential crack into a definite splitting of consciousness. It is not even essential that there should always be some physical or rather physiological, element in the case at all, not infrequently the psychical factor alone is sufficiently powerful not merely to predetermine the line of cleavage but actually to produce the complete split. Usually, however, the actual dissociation does not occur until some physical disturbance plays a secondary part in its production. This disturbance may be of a gross mechanical nature, as in some definite pathological lesion, or it may act simply by disorganising function, as in a metabolic or toxic disorder or an endocrine or circulatory change. A typical secondary mental state may be induced experimentally in predisposed subjects by the purely physical measure of compressing the cervical vessels; on the other hand, a mild but prolonged form of such a state is regularly induced by purely psychical methods in the treatment of suggestible patients under light hypnosis.

It is difficult to assess the part played by physical and psychical factors respectively in the production of

any given case of epilepsy. Those cases of grand mal in which genuine unconsciousness can definitely be established do not come within our definition of a secondary mental state, and remarks upon epileptoid phenomena of other types should not be applied to them. It does not necessarily follow that these remarks are altogether inapplicable, but for the moment this question is not raised. It is, however, recognised that unconsciousness as it occurs in grand mal may be quite independent of any gross physical derangement; in fact, it will admit of a purely psychical explanation.

The Conception of Dissociation.

Returning to those cases with which we are primarily concerned, it becomes evident that the phenomenon of dissociation in consciousness, considered as a psychological conception, becomes the crucial point in the whole subject. Propounded originally by Pierre Janet, the hypothesis was employed to explain the phenomena of somnambulism, hypnosis, dual personality, and all the paralyses, anæsthesias, and amnesias of hysterical patients. The conception of dissociation, as evidenced in these cases, was that of the process upon the molar scale, but soon it was found that its extension to the molecular scale provided a very helpful conception of psychasthenia, with its dominant subjective symptoms of doubt and depersonalisation. The symptoms of hysteria and psychasthenia were thus conceived by Janet to be manifestations of some disintegration in the totality of consciousness. Since normal mental processes depend upon the functional unity of the whole psychological apparatus, any such splitting or dissociation would obviously be incompatible with mental health; but whereas the analogy of dissociation furnishes a static conception of such processes, a more fundamental appreciation of the condition can only be reached by the adoption of the dynamic conceptions of Freud and the psychoanalysts, considered in conjunction with some hypothesis assuming a dissociative diathesis dependent upon some congenital lowering of psychological tension. The extension of the conception of dissociation so as to regard it as the fundamental condition responsible for all those phenomena subsumed under our definition and description of the "secondary mental state" is the thesis of this paper.

The practical application of these considerations is not that physical measures should altogether be discarded from the therapeutics of consciousness. It is, however, urged that when pharmacological and physiotherapeutic resources have been exhausted, it is at least worth considering whether investigation and treatment might not advantageously be directed along psychotherapeutic lines, even when the case can be classified in a non-psychogenic category.

Clinical and Laboratory Notes.

A NOTE ON THIRTY CASES OF CARCINOMA OF THE RECTUM TREATED BY GAMMA RADIATION.

BY CECIL P. G. WAKELEY, F.R.C.S. ENG., F.R.S. EDIN.,
ASSISTANT SURGEON, KING'S COLLEGE HOSPITAL;
AND
H. A. COLWELL, M.B., PH.D., M.R.C.P. LOND., D.P.H.,
DIRECTOR OF THE RADIOLOGICAL DEPARTMENT OF THE HOSPITAL.

BEFORE the development, by Neuman and Coryn of Brussels, of the open method for the insertion of radium in rectal carcinoma, first carried out in this country, we believe, by C. Gordon-Watson, the radium treatment of rectal carcinoma was generally held to be of little if any value. The unsatisfactory results obtained were due to difficulty of access, impossibility of uniform irradiation, inadequate control of lymphatic dissemination by suitable methods of arrage, the relatively slight difference between the adio-sensibility of the normal rectal epithelium and hat of the neoplasm, and the diminished sensibility f the growth due to septic changes. With these onclusions we agree, but hope that a short note upon 0 cases of inoperable carcinoma of the rectum treated t King's College Hospital from 1922 to 1927 may not e without interest, although in all cases the radium as inserted into the lumen of the bowel. All the ases were judged to be hopelessly inoperable, and dium treatment was adopted merely to render the atient's surviving space of life a trifle more tolerable. n every case a preliminary colostomy was performed. The quantity of radium salt ($RaSO_4$) used varied om 150 to 50 mg. and it was enclosed in torpedo-aped platinum iridium containers 0·5 mm. thick. hese were enclosed in another platinum iridium case, so 0·5 mm. thick. Each tube contained approxiately 50 mg. of radium sulphate, and one, two, or ree were used according to the dosage selected. The reened radium tube or tubes were enclosed in a soft bber tube before insertion into the lumen of the wel. It is clear from the filtration that the rectal oplasms were subjected only to gamma radiation. The duration of application varied from 12 to 30 hours.

The number of cases treated by the different quantities of radium were as shown in Table I.

TABLE I.

Cases.	Mg.	Hours.	Cases.	Mg.	Hours.
1	150	12	17	100	18
3	150	18	7	50	24
1	150	20	1	50	30

In the earlier cases, five in number, 150 mg. were used for 12, 18, 18, 18, and 20 hours respectively. In the first three reaction was severe, with pain, rise of temperature, and sloughing of the growth; the fourth, though showing but slight constitutional reaction at the time, died of secondary hæmorrhage in two weeks. The fifth case, where the radium was left in situ for 20 hours, showed but moderate reaction, and there was no appreciable ultimate effect on the neoplasm itself. The patient in whom 150 mg. were inserted for 12 hours, while exhibiting very marked radio-necrosis, subsequently developed definite fibrosis, but death ensued 12 months later with metastases in the liver and ascites. In all five cases the growth was situated at the lower end of the rectum.

TABLE II.

Amount of $RaSO_4$.	Duration of dosage.	Reaction.	Result.
100 mg.	18 hours.	Moderate.	Growth smaller. General improvement. Survived 18 months.
100 „	18 „	Very slight.	Marked shrinkage of growth. Died three years later with metastases in liver and ascites.
100 „	18 „	Very severe, sloughing and hæmorrhage.	Growth much smaller, excised six months later. Patient survived three years and died of bronchitis.

Seventeen patients were treated by the insertion of 100 mg. of radium sulphate for 18 hours. In nine of these the growth was at the rectosigmoid junction, and in only one of the nine was the smallest improvement noted. Here there was shrinkage and fibrosis of the growth and improvement of the general condition, but no prolongation of life. In the remaining eight

cases the growth was at the lower end of the rectum. Five of them showed improvement; in two there was slight fibrosis of the growth, but the general condition was improved. In the remaining three local improvement was definite and the general condition much improved (Table II).

In seven cases 50 mg. of radium salt were inserted for 24 hours. Three of these showed improvement, and one in which only a moderate reaction had occurred showed such marked retrogression that the growth was excised three months after irradiation. The patient survived three years and eventually died of heart failure. In two other cases the reaction was moderate, the growth diminished in size, and the general condition improved. The patients survived for 15 and 18 months respectively.

One case of carcinoma of the lower end of the rectum was treated with 50 mg. for 30 hours. A severe reaction, with hæmorrhage and sloughing, resulted; the growth, after showing an initial slight fibrosis, extended rapidly, and the patient died in 10 months.

All cases were histologically verified, the neoplasm being columnar-cell carcinoma. An interesting feature of this set of cases is the variation in the degree of reaction for the same dosages. In some cases definite radio-necrosis resulted and in others the reaction was not appreciable. The supply of radium available at the hospital is being redistributed in smaller containers, and it is hoped in the future to treat such cases by combined surgery and radiation for prolonged periods. Nevertheless, in view of the foregoing cases, it appears to us that when operative measures for the insertion of radium by the open method are inapplicable, the insertion of radium into the lumen of the gut may make the patient's condition more tolerable and under certain circumstances render a previously inoperable case operable. Our best results were obtained from the insertion of 100 mg. for 18 hours and of 50 mg. for 24 hours.

STRANGULATION OF A SLIDING HERNIA.

By HARRY GABB, M.B., B.CHIR. CAMB.,
SURGEON TO THE ROYAL EAST SUSSEX HOSPITAL.

ON NOV. 9th, 1928, late at night, I was called to the Royal East Sussex Hospital, Hastings, to see a man aged 80. He had a very large left-sided scrotal hernia, which was fairly tense and quite irreducible. He had vomited twice and was in pain.

He was anæsthetised and the usual incision was made parallel with Poupart's ligaments; the aponeurosis was divided over the inguinal canal and the obstruction at the external ring divided from above. The sac was opened; it contained colon which was connected to the posterior wall of the sac. Blood-vessels to the bowel came up from the posterior wall. It was obvious that this was a sliding hernia, invested by anterior and posterior layers of peritoneum from the left iliac region. The sac was freed entirely from its connexions, and the incision in it was sutured with catgut. The whole sac and its contents were then pushed back into the abdomen through the inguinal canal, which had been thoroughly opened up. As the patient had taken a great dislike to trusses, which he had probably put on over unreduced bowel, an earnest attempt was made at radical cure. His left testicle and cord were removed and the inguinal canal was entirely closed by deep sutures through conjoined tendon and Gimbernat's ligament; a further row united the external oblique aponeurosis. The patient healed well and at present has no hernia. At his advanced age I considered it worth while to sacrifice his testicle in order to close the canal; recurrence may not occur.

It is sometimes stated that these sliding hernias occur only in elderly men, but I saw three cases in men of military age, at the 73rd General Hospital in France, among the great number of ruptures that arrived there for operation.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

CLINICAL SECTION.

THE meeting of this Section on March 8th was devoted to the exhibition and discussion of

CASES OF ENDOCRINE DISEASE.

The chair was taken by Dr. J. WALTER CARR, the President.

Acromegaly.

The first case, under the care of Dr. C. WORSTER-DROUGHT, was one of Acromegaly. It was demonstrated by Dr. I. M. ALLEN. The patient was a man, aged 33, who reported that during the last six years his face and hands had been gradually increasing in size; also he had occasional headache and diplopia. Two years ago he had an injury to the back of his head, and following that there was paralysis of the left fifth, sixth, and seventh cranial nerves. The head and face, especially the soft parts, were now larger than the average. The size of the tongue had also increased, and there was some separation of the lower teeth. Hands and feet were typically acromegalic, and some kyphosis was noted. In regard to the eyes, the only points to be mentioned were a slight horizontal nystagmus to the right and a weakness of the left external rectus. There was slight facial paralysis of the lower neurone type. Marked changes in the sella turcica were revealed by X rays, the pituitary fossa being much enlarged and the bony margins indistinct. Wassermann was negative and the sugar tolerance normal.

Dystrophia Adiposo-genitalis.

Dr. HUGH STANNUS showed a boy, aged 13, who was the subject of Dystrophia Adiposo-genitalis. The boy was a full-term child, but he was illegitimate, and the history was that the mother had kept herself tightly laced to hide her condition. At two years of age he was ill-nourished and feeble, and learned to walk late. He was backward in speech, and until a year ago his habits were not good. During the last four years he had been somnolent and was readily fatigued. Periodically he drank large quantities of water and ate a good deal of sugar. Micturition was very frequent, and polyuria marked. The boy's weight was now 115 lb. The genitalia gave the appearance of pseudo-hermaphroditism, the very small penis being hidden by folds of fat, these folds resembling labia. There was a general muscular atonicity and it was difficult to elicit the knee-jerks. The mental condition was that of a child of 3, and he was difficult to control. There was no ocular paralysis nor albumin or acetone in the urine. The sella turcica was small and seemed to be surmounted by a cyst.

Dr. PARKES WEBER said that as the cyst seemed to be the most important factor in the case it might be possible, as a method of treatment, to break up the cyst and release its contents.

Sir JAMES DUNDAS-GRANT said that such a cyst had been reached by the sphenoid route.

Myxœdema.—Cretinism.

Sir JAMES DUNDAS-GRANT put forward a case of what he presumed was Myxœdema, in which the manifestations were confined to the palate and larynx. The young woman, aged 19, complained of thickness of the voice, a soft stridor on inspiration and occasional dysphagia, and came before his notice at Brompton Hospital as she was supposed to have tuberculosis of the larynx. There was found to be general thickening of soft palate and uvula and great infiltration of the epiglottis, which almost conceals the rest of the larynx. Wassermann was negative and the sputum contained no tubercle bacilli. A portion of the uvula removed showed no tuberculous or rhinoscleromatous tissue. Great improvement followed the giving of small doses of fresh glandular

thyroid substance, and the patient, after an eight-months' absence, returned to work. An increase in the dose cleared the voice, and there was a generally improved condition.

Dr. PARKES WEBER spoke of cases of localised puffiness, sometimes of actual œdema, of the legs in young women of the same age which had been known occasionally to yield to thyroid treatment.

Dr. H. V. MORLOCK showed a girl, aged 18, the subject of Sporadic Cretinism. The birth was a normal one, and the child walked at the age of 16 months, and was able to talk at 2 years. At 3 it was noted to be getting fat and listless, sat for long periods without playing, and forgot to eat. At 5 years of age her height was 35 in. and there had been no increase by the seventh year. At 7 years of age thyroid treatment was begun, and then development started. Thyroid had been continued ever since. Her height was now 5 ft., and her mental development was fair. In reply to the President, Dr. Morlock said she was now taking grs. 2 of dried thyroid extract daily. Her pulse did not rise now beyond 80, and she was not losing weight.

Dr. E. A. COCKAYNE considered that this case should be called one of juvenile myxœdema.

Pituitary Deficiency.

Drs. E. P. POULTON and E. C. WARNER showed a woman, aged 27, with Deficiency of the Anterior Lobe of the Pituitary. The mother was 5 ft. 3 in. in height, the father somewhat taller. The weight of the child at birth was 5 lb., but she was not backward in sitting up or walking. Mentally she was rather slow, but could read, write, and play the piano. Her first menstruation occurred at her twenty-fourth year, and it usually lasted six days. Sometimes she missed a month. Thyroid swelling was first noted at the age of 6 months, and at 3 years it was so extensive as to demand operation because of pressure symptoms. Indeed four operations had been done for this reason, the last seven years ago. Sections of the gland showed parenchymatous goitre with but little colloid. At present a large swelling in the right lobe of the thyroid displaced the trachea a good deal to the left. Fields of vision were normal, and the pituitary fossa was of the usual size. Some of the epiphyses had not yet joined. The sugar tolerance was normal, and the basal metabolic rate was from 9 to 12 per cent. below the normal. Increasing doses of thyroid and whole pituitary gland had brought about much improvement. The two menstrual periods which occurred since had been normal, she had gained 5 lb. in weight, the thyroid swelling was much less, and the patient had become brighter and happier.

The PRESIDENT raised the question whether, in this case, there was a relationship between the undoubted thyroid disease and a probable diseased condition of the anterior pituitary body.

Dr. G. SLOT, speaking of the methods of giving the remedies, said that at London Hospital Dr. O. Leyton and he tried the effect of giving pituitary extract by the mouth, and by the subcutaneous method in cases which could be controlled by the output of urine. Various oral preparations of the pituitary gland were used, but they had no influence on the urinary output, whereas when the subcutaneous route was employed there was immediate improvement. He did not see any evidence of a pituitary factor in the present case; the thyroid condition probably accounted for all the symptoms.

Dr. PARKES WEBER said he had not heard that pituitary given by the mouth had done any good in cases of pituitary dwarfism.

Dr. COCKAYNE agreed with Dr. Slot that probably in this case the thyroid deficiency accounted for the condition.

Dr. W. S. M. COPEMAN referred to three cases of pituitary deficiency which were studied at Great Ormond-street Children's Hospital by Dr. F. J. Lynton. The latter had concluded that pituitary extract given orally when combined with thyroid extract—though the latter did not seem to be indicated—was a success so long as the administration was being continued.

Dr. WARNER, in reply, referred to the lectures by Harvey Cushing, given three years ago, on endocrine disorders. In certain of the cases there alluded to benefit followed the giving of pituitary, apart from thyroid, and the benefit was sexual as well as general. Following Dr. Gardiner Hill's work, the speaker had tried, in the case of some of these fat people, giving whole pituitary gland alone, also thyroid gland alone; and his general impression was that a larger drop in weight occurred over a given time when the two treatments were combined.

Graves's Disease.

Mr. A. HOBSON (for Mr. Mortimer Woolf) showed a case of Probable Graves's Disease with Thyrotoxicosis. The man, aged 28, first seen four months ago, said his thyroid had been getting large for six weeks. For five weeks his eyes had been very prominent and staring. Both lobes of the thyroid were much enlarged. On admission the pulse-rate was 84 and regular. He did not feel sure that this was Graves's disease. The man was put to bed, and later had a rise of temperature and severe sore-throat. Swabs did not reveal any diphtheria bacilli. Subsequently he lost about 3 lb. weekly in weight, and there was a definite loss of sugar tolerance. The pituitary fossa seemed to be normal. Recently there had occurred a diminution in the thyroid swelling. He was now being treated with glucose and insulin.

Dr. D. E. BEDFORD considered that this patient showed all the usual symptoms of Graves's disease, except that the pulse-rate was 84. Still, a slow pulse did not necessarily mean the case was not Graves's disease; there might be heart-block present. This patient now had auricular fibrillation. If the normal rhythm could be restarted and the general condition improved, he considered that removal of the right lobe was indicated.

Mixed Endocrinopathy.

Dr. I. M. ALLEN showed (for Dr. Worster-Drought) a case of Endocrinopathy of Mixed Origin. The patient was a young woman aged 25, who, when seen, was tired, slow at her work, and of poor appetite. Mental dullness had been increasing for four years. Obesity was first noted about the chest and hips. A year ago she had fits of screaming and noisy hysterical attacks. Menstruation was always irregular. Her frontal and malar bones were prominent; the lower jaw was large and protruded beyond the upper jaw. The hair on the head was profuse and thick, axillary hair was extensive. Pubic hair was normal, but extended to the umbilicus. The cerebro-spinal fluid was normal. Systolic blood pressure was 120, diastolic 75; the sella turcica was not abnormal. Following treatment with extract of whole pituitary and thyroid extract in 3-gr. doses once a day, the weight of the patient was reduced in three weeks from 175 lb. to 164 lb. She became brighter and more sociable, and could carry out small duties satisfactorily. Opinions were asked as to the diagnosis. Conditions other than those of endocrine origin had been carefully considered, such as dementia præcox, post-encephalitic disorder of the pituitary, &c., but no evidence existed to support any other diagnosis. It was regarded as a thyro-pituitary case.

Three Cases of Dyspituitarism.

Dr. WORSTER-DROUGHT and Dr. C. ARCHER exhibited: (1) Dyspituitarism of Mixed Type; (2) Dyspituitarism of Fröhlich Type with Extreme Genital Dystrophy; (3) Dyspituitarism of Mixed Type.

The first of the patients was a boy, aged 15, who was brought to hospital because of his unusual size for his age, his obesity, difficulty in walking, attacks of vomiting, and his mental backwardness. He did not begin to walk until 3 years of age, then he grew rapidly and became obese. He had a large appetite and was very fond of sweets. His height was 6 ft. 1 in., weight (stripped) 19 st. 8 lb. His temperature was always subnormal. The blood pressure was 125

systolic, 75 diastolic. The sella turcica was somewhat small, the frontal sinuses unusually large.

The second patient was a boy of 9, the youngest in a family of six, the other five being normal and in good health. This sixth was a full-term child, and his size seemed normal until 2½ years of age. From that age onwards, obesity had been steadily increasing. The adiposity was general. The temperature was almost always subnormal. The scrotum was completely absent, and no external evidence of testicles could be found. A small penis was present, and was traversed by the urethra. Mentally the boy was somewhat backward, and his habits were dirty. The sella turcica seemed normal; the urine contained neither sugar nor albumin. The blood showed an increase in the large lymphocytes. The blood Wassermann was negative.

The third patient in this series was a girl, aged 10. She was noticed to be getting obese at about 4 years of age, and it had progressed steadily, and during the last four years she had been increasing in stature. She was drowsy, slept a good deal, and said she could go to sleep at any time. The adiposity in her case was mostly round the pelvic and pectoral girdles. The average temperature was subnormal, but the heart was normal. The sella turcica did not appear abnormal.

Obesity.

Dr. TERENCE EAST exhibited a female patient, in the early twenties, the subject of Obesity of Thyroid Origin. The rate of increase in weight had been rapid, she having put on 6 st. in a few months. She had shed her eyebrows, her skin was dry, her feet felt tired, and she was lethargic. There was no change in the thyroid. Her cardiovascular system was normal.

The PRESIDENT considered this to be more like a pituitary case. The patient apparently had very severe headaches while the obesity was developing.

Dr. PARKES WEBER suggested, as an alternative, that it might be premature fibrosis of ovaries.

MEDICAL SOCIETY OF LONDON.

AT a meeting of the Society held on March 11th, Dr. WALTER CARR, the President, in the chair, a discussion on the

CHRONIC DYSPEPSIAS OF CHILDREN OVER THE AGE OF INFANCY

was opened by Dr. REGINALD MILLER. His first intention was, he said, to compare the chronic dyspepsias of children with similar conditions in adults. There was one striking difference between them—namely, the much less important part which was played in the children by the stomach. In the chronic dyspepsia of children local abdominal pain was much less important than in grown people. In the former there was little of the regularly recurring pain, having a definite time relation to meals; indeed, it had a closer relation to actions of the bowels. In children the main symptoms of the condition were those of a constitutional type: lethargy, lassitude, loss of appetite, a coated tongue, foul breath, &c., and particularly general loss of health and alterations in the child's character and behaviour.

Usually the dyspepsias of childhood were divided into the gastric, the hepatic, the intestinal. The gastric were further divided into organic, reflex, and functional. The practical absence of ulcer and growth in childhood brought the organic causes down to small limits. Even chronic gastritis was a comparative rarity in the young, in spite of the frequent use of a faulty diet. Of the reflex kind there was practically only chronic appendicitis to consider. This was debated before the Children's Section of the Royal Society of Medicine, where the general opinion was expressed that though recurrent appendicitis commonly produced recurrent gastric symptoms, yet very little was known of chronic appendicitis producing chronic gastric dyspepsia. He thought that in a general way that verdict would be accepted. Regarding functional gastric dyspepsia in children, much less work had been done in investigating the gastric function in children than in adults, although Dr. W. S. Copeman had recently tried to establish a normal secretory curve, while another worker had come to the conclusion that hyperchlorhydria was a common cause of dyspepsia in children. Symptoms of atonic dyspepsia, of mild grade, were common in debilitated and constipated children, and cases of considerable severity, with a splash and a dropped stomach, were found in weakly children of considerable age. Also there was a very rare type of case, with a dilated and hypertrophied stomach, almost warranting the name gastromegaly. The causation of this condition he did not understand. He did not feel clear about the occurrence of hepatic dyspepsia, though it was true that in chronic indigestion there was often evidence of hepatic derangement. These episodes, however, were probably due to doses of intestinal toxæmia, with secondary disturbance of the liver.

With regard to acidosis and the part it played in association with digestive disorders, it had long been recognised that acid intoxication was associated with periodic gastric symptoms, such as cyclical vomiting, but the latter was not included in the present discussion strictly. But Dr. H. C. Cameron claimed that many cases with chronic symptoms, mostly nervous, but also abdominal, were due to acidosis, though the acidosis on which Dr. Cameron built his theory was not of the type associated with persistent ketonuria; it was a latent acidosis, distinguished by a lowering of the alkalinity of the blood. Dr. A. A. Osman had recently said that 30 per cent. of hospital children suffered from cyclical vomiting. Excluding the consideration of recurrent attacks of cyclical vomiting, there were a large group of cases exhibiting the triad of symptoms: (1) constitutional ill-health, apparently due to chronic toxæmia; (2) nervous disorders probably functional; (3) persistent dyspeptic abdominal symptoms, such as colic, diarrhœa, mucus in the stools, and so forth. He believed Dr. Cameron considered the constitutional factor to be due to latent acidosis, the digestive symptoms being secondary. It was presupposed that the child started with an emotional and neurotic condition. The speaker found it difficult to accept those views, as he did not see how slight latent acidosis could produce persistent and chronic symptoms; moreover, small doses of an alkali would do away with such acidosis. Some children having acidosis were yet well and free from nervous symptoms. His own view was that there was first intestinal indigestion, then toxæmia arising from that; then constitutional ill-health and nervous symptoms arising as a result of the intestinal toxæmia. These views differed in their assignment of the primary source of the trouble, and therefore in the treatment adopted to deal with it.

In intestinal indigestion the symptoms were not always those suggestive at first of a disorder of digestion; in many cases the general constitutional and nervous symptoms overshadowed the abdominal signs and symptoms; these children had an unhealthy looking, muddy complexion, puffy face, dark rings round the eyes, a coated tongue, foul breath, a strong odour from the body, loss of appetite, and were easily fatigued. They might have nocturnal fever, and sweating at night was common; the nerve manifestations took the form of a profound psychological upset. This kind of child was recognised by several signs. There was an enlargement of the abdomen, which might be persistent or intermittent. Flatulence and hiccough were common. There was the occasional or persistent occurrence of abnormal stools, and when the stools were most markedly abnormal it could be seen that there was a deterioration in the child's condition. Another proof of gross indigestion was furnished on microscopical and chemical examination of the fæces, and there was indican in the urine.

Starch indigestion was not a common fault in older children; it could be suspected when

stools were loose and acid and were pitted from the evolution of gas. Signs of secondary colitis might be present. These cases were due to over-feeding with starch. Paraffin indigestion had to be reckoned with; it was due to overdosing with medicinal paraffin. The oil surrounding the particles of food favoured decomposition rather than digestion. Likewise there was a "nut indigestion," in which vegetable cells surrounded by the nut oil were found; he thought some of the new bran preparations produced a similar condition. Pale fatty stools might be simply the result of the undue intake of nut food. With regard to threadworms, apart from the local irritation he knew of no difference in the toxic constipation with threadworms and that without them.

Dr. Miller concluded by discussing the causative factors in intestinal toxæmia. Why was one constipated child in good health, while another similarly constipated was obviously ill from toxæmia? In many cases in children alimentary toxæmia was not associated with intestinal stasis, and very little was seen of cæcal stasis and distension in children. From the examination of 2000 cases he was unable to correlate toxæmia with any quantitative changes in the intestinal flora. The worst cases seemed to be those in which the streptococcal count was high and the coli count low. But who could tell whether those changes were the cause or the result of the intestinal disorder? He considered that colitis was set up not so much by abnormal bacterial poisons as by chemical factors, among them the prolonged use of unsuitable aperients, of irritating foods, and perhaps the passage and pressure of hard fæcal masses. On the colitis much of the toxæmia, he considered, depended. If this were so, it gave an indication of the lines to pursue—giving a smooth residue diet, non-irritating aperients, and colon lavage.

Gastric and Intestinal Symptoms Contrasted.

Dr. W. G. WYLLIE said one of the most striking features of these digestive disorders in young children was the close interplay between the gastro-intestinal and nervous systems. In the dyspepsias mainly intestinal in origin the nervous symptoms so far outclassed those related to the bowel, that it was the nervous manifestations which chiefly coloured the mother's picture of the child's ailment, though they were secondary to the bowel disorder. In the case of gastric disorders—of which vomiting was the chief symptom—probably the reverse was the case. The liver must have an important rôle in all the dyspepsias, but the testing of hepatic functions had not yet reached a stage to be of much use in recognising the effects of intestinal and metabolic toxæmias. To this, however, cyclical vomiting was an exception. Another remarkable feature of the cases under discussion was the abundant manufacture of mucus in the gastro-intestinal tract, in constipated cases as well as those with a tendency to diarrhœa. He divided the chronic dyspepsias of childhood into two groups—those mainly concerned with the intestine, and those in which the gastric functions were most obviously affected. In the first group he placed chronic intestinal dyspepsia, mucous disease, cœliac disease, colitis; in the second group he put bilious attacks, cyclical vomiting, and gastric disorders of definitely nervous origin. Some of these were simply clinical entities; there was no strict definition of them scientifically considered. Chronic intestinal dyspepsia he regarded as especially a disorder of the urban child population of the hospital class, and the chief causes seemed to be external; they had hurried and inadequate meals, and there was a constant nervous irritability. Fainting attacks might occur, also somnambulism. Often there were signs of vasomotor disturbance, such as cyanosed and clammy extremities and enuresis. Sometimes tuberculosis was suspected by the parents. Many cases presented an irritative papular rash in the form of lichen urticatus, chiefly on the trunk and lower extremities. Many of these children had morning retching, due to the collection of mucus in the stomach during the night. Chronic intestinal dyspepsia responded readily to treatment—i.e., a proper adjustment of diet on physiological principles, and continued use of mild laxatives and sodium bicarbonate. Mucous cases also required a proper constitution of the diet, and the improvement of the bowel condition by small doses of hydrarg. cum crete, sod. bicarb., and bismuth salicylate.

Most cases of cœliac disease started towards the end of the second year of life, and it was a very chronic condition. The stools were numerous, pale, bulky, and often frothy; in severe cases there might be streaks of blood in them. These children found it very difficult to assimilate fats and carbohydrates, yet there was no evidence of a pancreatic or hepatic deficiency. Dr. Hutchison had determined the urea production in these cases; it was normal. Two views had been advanced as to the cause of this condition: one favouring a bacterial origin, the other suggesting a purely metabolic disorder. Dr. Wyllie considered that in every case of cœliac disease it would be well to examine the stools for dysentery bacilli, and to have the agglutination reactions of the blood serum investigated. There were strong reasons for suspecting a bacterial agent in cœliac disease, and family cases suggested that the disease could be transmitted from person to person. The question arose whether it was possible that fat was absorbed in cases of cœliac disease and again excreted without being utilised. Bauer had found the blood-fat raised in cases of cœliac disease, quite apart from its cholesterol content. Still, this idea of it being a disorder of fat metabolism must be accepted with reserve, as methods of estimating blood-fats had not been standardised. His own view was that in this disease there was a defective absorption of fats owing to the action of bacteria, probably of the dysentery group.

Bilious attacks were characterised by frequent vomiting for a day or two, often associated with fever and headache. The subjects of it were often decidedly nervous children, and the onset of the attack was often heralded by apathy, irritability, a distaste for food, &c. Usually, there was an underlying state of chronic intestinal dyspepsia. The periodicity of the attacks led to the view that the vomiting was produced by the action of absorbed toxins on the cerebral centres, rather than by gastric catarrh or disability. There seemed to be a close relationship between bilious attacks, cyclical vomiting, and migraine. In cyclical or recurrent vomiting several theories of causation had been put forward, and these the speaker discussed. Certainly the children in whom it occurred were of a nervous temperament.

With regard to dyspepsias in general, McCarrison had stated that they were probably connected, in their origin or in their continuance, with dietetic deficiency and a lack of balance in the food. Mellanby, working on the subject of diarrhœa and vomiting in children, thought that the diarrhœa and vomiting facilitated the entry into the body of toxic substances which were normally present in the intestine.

Discussion.

Dr. B. E. SCHLESINGER said that the ætiology of these conditions was still imperfectly understood. He favoured the view put forward by Dr. Wyllie as to the cases of cyclical vomiting. The speaker had recently seen two cases, in one of which migraine, cyclical vomiting, and attacks of vaso-vagal character, similar to epileptic attacks, occurred. In that child he was able to banish the fits by dietetic measures, by increasing the carbohydrates and decreasing the fats. The explanation of these cases was thought to lie in a temporary anæmia of certain parts of the brain. As a routine, in these cases, he took a record of the blood pressure, and in a certain number of migrainous cases there was a distinct rise in the blood pressure. He did not think all cases of migraine and cyclical vomiting had hyperpiesia. He wondered whether the cases of "nut dyspepsia" mentioned could not be put in the same class as those of quaker oats and coarse wholemeal bread—i.e., foods causing intestinal irritation in children. In colitis there was

not much quantitative alteration of intestinal bacteria found. The speaker wondered whether the production of mucus was not a defensive mechanism of the body. In dysentery, especially late stages of it, an enormous quantity of mucus was passed. It might be a measure of protection against roughage of the intestine by irritating foods.

Dr. F. G. CHANDLER referred to the varying advice sometimes given concerning the same type of case by different children's disease specialists, and asked as to what constituted good breakfasts and teas for children.

Dr. W. S. COPEMAN suggested that the cause of the conditions being discussed was not any diathesis, but that the ground was prepared in early life by various dietetic and therapeutic measures to which the infant had been subjected. Light might be thrown on the matter by studying the effects of diets in children of other countries where other habits prevailed. On the continent a higher carbohydrate diet was favoured for the infant, 10 per cent. being given in milk mixtures in the hospitals. In the adult state the Frenchman was less liable than the Britisher and the American to hyperchlorhydriac dyspepsias.

The PRESIDENT remembered, when many years ago he saw out-patients, the large number of children whom he diagnosed as suffering from muco-membranous catarrh. Measles, he thought, played a very important part in producing chronic dyspepsia in children. The more important respiratory sequelæ of that disease were well known and recognised, but he thought the gastro-intestinal results of that disease were even more numerous than the respiratory.

Mr. ZACHARY COPE commented on surgical causes of chronic dyspepsia, such as chronic appendicitis. Chronic tuberculous glands in the abdomen, either calcifying or non-calcifying, gave rise to attacks of colicky pain simulating that of dyspepsia. X rays would show the calcification, and so help to a diagnosis. If these glands were not diagnosed early and dealt with acute intestinal obstruction might result. Also, chronic intussusception might go on for weeks and be mistaken for chronic dyspepsia of doubtful origin.

Replies.

Dr. MILLER said that those who declared cœliac disease to be an infection should have a clear conception of what the infection was doing. What seemed to point to malabsorption of fat was the fact that long after the symptoms disappeared the fat absorption still remained defective.

Dr. WYLLIE thought the most hopeful research was along chemical lines. The child's breakfast should be somewhat varied from day to day; suitable ingredients were rusks, force, grape-nuts, shredded wheat, a lightly boiled egg, bread-and-butter, bacon, and jelly. More important still was a dose of orange juice before breakfast, both for its relaxing effect and for its contained vitamins.

A HOSPITAL AMALGAMATION.—It has been decided to amalgamate the Devon and Cornwall Ear and Throat Hospital with the South Devon and East Cornwall Hospital at Plymouth. The arrangement is, however, unlikely to become immediately effective, owing to the need for enlarging the accommodation of the larger institution.

DONATIONS AND BEQUESTS.—Mrs. Alice Pigott, of Hove, left £1000 to the Cancer Hospital, Fulham; £300 each to the Royal Hospital for Incurables, Putney, the National Hospital for the Paralysed and Epileptic, and the Solicitor's Benevolent Association; £200 each to Dr. Barnardo's Home for Cripples, Tunbridge Wells, the Church of England Waifs and Strays Society, the Royal United Kingdom Beneficent Association, Charing Cross Hospital, and the Royal Free Hospital.—The Nizam of Hyderabad has given a donation of £1000 to the Ross Institute and Hospital for Tropical Diseases.—Among other bequests the late Mr. J. R. Pope, of Wotton, Gloucester, left £5000 to the Gloucester Royal Infirmary and Eye Institution, and £1000 each to the Bristol Royal Infirmary and the Free Hospital for Children of the Poor at Kingsholm.

Reviews and Notices of Books.

THE PROBLEMS OF APPLIED ENTOMOLOGY.

By ROBERT A. WARDLE, M.Sc., Professor of Zoology, University of Manitoba. Manchester: University Press. 1929. Pp. 587. 30*s*.

THIS work does not aim at being complete in itself but is intended to supplement the volume on Principles of Insect Control, published by Wardle and Buckle in 1923. The first part of the book consists of a review of general problems, and is in fact a consideration of the physiology, œcology, pathology, and toxicology of insects in their relation to insect control. The problems of agricultural entomology are so abundant that it is only natural that they should usurp by far the greater part of the space available. But this makes the book no less stimulating for the medical entomologist, and it is certainly of value to find, set out side by side, such theories as Uvarov's "Phase Theory" of locust migration and the theory outlined by Roubaud and Wesenburg-Lund, of zoöphilous races of anophelines, each involving the idea of biological races characterised by their behaviour. The practical value of the study of insect physiology comes out very clearly in this book, albeit that so far it is mainly such fields as temperature and humidity effects and tropistic reactions which have been exploited. In connexion with "oviposition stimuli," reference might well have been made to the experimental studies of P. A. Buxton and G. H. Hopkins on oviposition by *Aëdes* (*Stegomyia*), for these studies point very clearly the moral of the need for adequate controls and for the statistical examination of results.

The second part of the work represents an attempt to compress into a space admittedly too small a summary of the main entomological problems which exist in all parts of the world at the present day. The arrangement is geographical and the result is a most valuable piece of work. The brief summaries of medical entomological problems are adequate for the most part, though rather less than justice has been done to the work of S. Adler and O. Theodor and others on oriental sore. The mode of transmission of louse-borne relapsing fever was originally demonstrated by C. Nicolle and others in 1913 and not as here stated by Shapsheveka in 1924. Part III. (40 pages of small print) consists of a classified bibliography which purports to be complete for the period under review. The book does not set out to be critical and it contains too many facts to make easy reading, but as a work of reference it will be a essential possession for the agricultural entomologist and the medical entomologist will find it of considerable value.

OLD MASTERPIECES IN SURGERY.

Being a Collection of Thoughts and Observations engendered by a Perusal of some of the Works of our Forebears in Surgery. By ALFRED BROWN, M.D. Omaha, Nebraska (privately printed). 1928. Pp. 264.

FORTY-EIGHT papers are here reprinted from the corner of *Surgery, Gynecology, and Obstetrics* known as the "Surgeons' Library"; they represent a output of one a month over four years. The author modestly disclaims in his preface any pretentions to being a medical historian, but his studies on the incunabula of surgery are on the way to making history; he does not profess to deal exhaustively with his subject, and he has written short essays, mainly round the title pages of the works of our forefathers, from Soranus of Ephesus and Oribasius of Sardis through those of mediæval times, and ending with Cheselden. To try to recreate the personality of surgeons of past generations from a study of their works is, in most instances, the only way. All down the ages surgeons seem to have been as conscious of

each other's deficiencies, to quote the dictum of the late Lord Justice Bowen, as any bench of Her Majesty's judges—vide Ambroise Paré and "mon petit maître" Gourmalen.

How great a part war has played in the evolution of the surgeon is emphasised by the author. As means of killing advanced it became necessary for the surgeon to adapt his methods of treatment to new kinds of wounds. Nothing is said here about the hand-to-hand scuffles of the men of the Stone Age, but we are introduced to the feudal cavalry, heavily armoured both man and horse, suffering mainly from head injuries and fractures due to the lance, mace, and battle-axe; we are told of the arrow wounds resulting from the short bow of Norman times, and we recognise the much more severe wounds resulting from the Edwardian institution of the long bow, where the bowstring was drawn to the lobe of the ear, thus making it a far more potent engine of destruction and, incidentally, making the English archer by far the finest foot soldier of the times. Later on came the crossbow with quarrel, and gunpowder with the harquebusse, musket, and rifle, and finally high explosive. By an oversight, the date of the Black Death, in the essay on John of Arderne, is post-dated 20 years; it should be 1348–49. Praise is due to the author for the skill with which he has marshalled his material; the illustrations of title pages of incunabula and of old surgical instruments are beautifully reproduced and the essays, while certainly not exhaustive, are well written in a pleasant style.

REPORT ON MUSSEL PURIFICATION.

By R. W. DODGSON, M.D., M.R.C.P., M.R.C.S., Director of the Ministry of Agriculture and Fisheries Research Station, Conway. London: H.M. Stationery Office. 1928. Pp. 498. 21*s*.

IN addition to a description of a new method of purification for mussels on a large scale, the report contains a valuable discussion on shell-fish pollution, poisoning from mussels, bacteriological methods of examination, and much information about particular mussel beds. The discussion upon the sources of pollution of mussels and other shell-fish and the evidence as to disease conveyance will be of great interest to those concerned with public health problems. Much obscurity surrounds the question of mussel poisoning, of which an excellent and detailed account is given, valuable material not readily accessible being collected from varied sources. The author divides mussel poisoning cases into three groups. There is, first, the erythematous type which he describes as "musselling," associated with an erythematous rash, often with urticaria and other symptoms, and now usually considered to be of anaphylactic type. The second is the paralytic type, and includes very fatal, but fortunately rare outbreaks of puzzling ætiology. Some eight or ten such outbreaks are described. They used to be ascribed to *mytilotoxine*: the author agrees that this theory is now discredited or at least not proven, but he throws no light on their causation. Dr. Dodgson is somewhat unfortunate in that his volume was written before the only modern report on such an outbreak was issued. We refer to that dealing with the extensive outbreak on the Pacific Coast in the neighbourhood of San Francisco where 102 cases and six deaths occurred. The outbreak was described by Meyer, Sommer, and Schoenholz,[1] and adds much new information as to the cause of the poisoning. The third type is bacterial food poisoning, which rarely follows the consumption of mussels, but cannot be excluded.

A long series of experimental investigations culminating in the elaboration of a simple method of purification of mussels is described by Dr. Dodgson. In its essentials this consists of allowing the shell-fish to purify themselves by short sojourns (two baths each of one night) in tanks of sterile sea-water with a third treatment with chlorinated water to kill any bacteria on the shells. The mussels are then packed in sterilised bags ready for the market. The utility of this method is demonstrated by numerous bacteriological investigations, nearly complete sterility being attained. The economic side of the process is discussed and it is shown to be a practicable procedure from the economic aspect. Very many other problems are dealt with in the report, such as the life-history of the mussel and its habits, bacteriological examination, bacteriological standards, and the like. The general bacteriologist will find much to interest him in these sections of the report. Many points discussed are highly technical; for example, the author finds that lactose-containing culture media are unreliable for primary shell-fish examinations, the reason being that glucose is produced from mollusc glycogen by enzyme action. The vexed question of bacterial standards for shell-fish is discussed in detail; such standards are regarded merely as indications that contamination is liable to occur.

The whole report is a useful piece of work reflecting great credit on the author.

TRIAL OF J. B. RUSH.

Notable British Trials Series. Edited by W. TEIGNMOUTH SHORE. London and Edinburgh: William Hodge and Sons. 1929. Pp. 272. 10*s*. 6*d*.

RUSH, the Norwich murderer, killed his landlord, Isaac Jermy (recorder of Norwich) and his landlord's son one night in 1849. He owed Jermy a large sum, had no money, and had soon to pay off a mortgage on his farm. Having forged documents which might help him financially if Jermy's death occurred forthwith, he went up to Stanfield Hall partially disguised and shot the inmates. With four bullets he murdered the father and son and wounded Mrs. Jermy and a servant. Cunning enough to lay a false trail of suspicion, he was too stupid to see that the attempt to cover his tracks merely made his conviction more sure. This adequately edited volume has less medico-legal interest than many of the series to which it belongs. Rush, defending himself unaided and haranguing the jury vigorously, makes a notable figure. After his wife's death he had engaged for his children a governess whom he seduced under promise of marriage. The poor woman, truculently cross-examined by the accused, gave evidence of his movements and conduct which went far to establish his guilt. Had he kept his promise and married her, that evidence could not have been given and he might have saved his neck.

THE MACHINE OF LIFE.

By ETHEL BROWNING, M.D. London: William Heinemann (Medical Books), Ltd. 1928. Pp. viii. +124. 5*s*.

THIS latest addition to the increasing number of books presenting physiology and anatomy from the popular point of view has much to recommend it. The author has not only covered the traditional grounds of describing the anatomy and physiology of the various systems, but she has included an excellent chapter on reproduction and one on the mind as distinct from the nervous system. On the whole the subject matter is presented clearly and accurately but in places revision is necessary. The arrangement of headings throughout could be improved. The last half a dozen lines on the ear (p. 41) do not make sense, while the heart is described under the heading of "The Lymphatic System." The description of the heart as "placed obliquely," and later on as "divided horizontally" and "divided vertically" makes very confusing reading (pp. 63, 64). The book gives the impression of having been put together too hastily, but the author certainly has that ability to describe technical details in simple language which is the essential quality in the production of a book of this kind.

TEXT-BOOK OF PATHOLOGY.

Second edition. By ROBERT MUIR, M.A., M.D., Sc.D., LL.D., F.R.S., Professor of Pathology, University of Glasgow; Pathologist to the Western Infirmary, Glasgow. London: Edward Arnold and Co. 1929. Pp. 872. 35*s*.

THE primary object of this book was to provide for medical students a text-book dealing on the one hand with the scientific aspect of general pathological processes, and on the other with the systemic pathological changes of special importance in relation to clinical medicine and surgery. In the preparation of the second edition Prof. Muir has wisely kept this object in mind and has not altered the general plan of his book. This edition is larger by a hundred pages than the first, and contains about seventy additional illustrations, but this enlargement is the result of the judicious incorporation of new matter and the careful revision and expansion of the text.

When it first appeared Prof. Muir's book was recognised as the most important publication of its kind in this country. Its popularity has continued to grow, for it has the peculiar merit that the more it is consulted the more its excellence becomes apparent. In no other book of its size with which we are acquainted is the lucid presentation of general principles combined with such a wealth of detailed information. The care with which the second edition has been prepared can only be appreciated by a close study of the text; but such an examination will show that almost every page has been passed under review. The result is not only an admirable text-book but a work of reference which should be in every pathologist's library.

PRACTICAL BIOCHEMISTRY FOR STUDENTS.

By E. W. H. CRUICKSHANK, M.D. Aberd., D.Sc. Lond., Ph.D. Camb., M.R.C.P. Lond., Professor of Physiology, Prince of Wales Medical College, Patna. Calcutta: Butterworth and Co., Ltd. 1928. Pp. 275. 12*s*. 6*d*.

THIS work appears to be exceptional in that the author has broken away from the standard of somewhat depressing experiments which usually form the subject matter of text-books of practical biochemistry and chemical physiology. The first few chapters are devoted to a brief description of laboratory equipment, standard solutions, and so forth, together with some general directions to the student. Then follow three chapters which give fairly detailed accounts of proteins, carbohydrates, and fats in turn, details of tests for the substances coming under these headings being given. The digestive processes are next dealt with fully, a short chapter being included on bile. Chapters VIII. and IX. deal with the urine; full accounts of qualitative and quantitative examinations are given, and in many cases alternative methods are described. Chapter X.—a short one on the chemistry of foodstuffs—has been completely omitted from the table of contents, upsetting the numbering of the subsequent chapters in the text. The last 50 pages of Part I. deal adequately with the blood and its chemical analysis. Of special interest is the chapter on the neutrality mechanism of the blood in Part II. This is very well written and goes into some of the more difficult and complicated aspects of the subject. It commences with a detailed description of the colorimetric method for estimation of pH of the blood, followed by a brief but clear account of theoretical considerations. The author, we think, has handled the mathematical aspects of the subject very cleverly indeed, and he has written an account which should be easily understood even by one who finds mathematics difficult. The difficult subject of buffers is also tackled from a modern standpoint. A short series of references to this part of the book is given, and the appendix includes some useful tables.

The volume is small and well arranged, and gives a concise account of the subject matter with refreshing originality.

CLINICAL RADIO-DIAGNOSIS OF THE INTESTINAL CANAL.

By H. CHAOUL. Berlin: Julius Springer. 1928. With 893 illustrations. Pp. 642. M.48.

MANY books have come to us from Germany in the last few years, but this volume is outstanding and is likely to become a classic in the literature of the gastro-intestinal canal. The illustrations show a very high order of radiographic technique and are very well reproduced. The technique of the author differs slightly from that in general use, but seems to be effective both from the radiographic and screening point of view. The manner in which he uses looking-glass observations for screening and radiographing the duodenum is simple and, judging by the radiographic results, efficient.

That such a splendid book should be put up in paper covers and published with uncut pages is a curious example of misplaced economy. We were so impressed, after a brief survey, with the value of the contents, that the rebinding of the volume in a manner more worthy of the enormous labour and high achievement of the author seemed imperative. The publishers have used art paper throughout, and the radiograms have been extremely well reproduced. After rebinding it is now a first-rate volume in every way, the letterpress being clear, not redundant, and well arranged.

MALAY POISONS AND CHARM CURES.

Third edition. By JOHN D. GIMLETTE, M.R.C.S., L.R.C.P. London: J. and A. Churchill. 1929. Pp. 301. 10*s*. 6*d*.

THE first edition of this book was published in 1915 and was quickly sold out of print. It took rank as an authoritative pronouncement on forensic medicine in the local law-courts, and a second edition was produced in 1923. The third edition has been brought up to date, but much research still remains to be done in working out the physiology and toxicology of some of the poisonous plants which abound in Malay. The Borgias and other celebrated poisoners of the past would have revelled in the possession of such a collection of obscure poisons. The book is divided into two parts, the second of which is devoted to the poisons obtained by Malays from fish and other members of the animal kingdom, from jungle plants and other vegetables, and those derived from inorganic sources, such as arsenic, mercury, cyanide of potash, pounded glass, sand, and quicklime. This part of the book is of real scientific value. An appendix gives examples of spells and charms transcribed into Romanised Malay, a classification in natural orders of the poisonous plants, and a list of Kelantan poisons.

The first section of the book forms a treatise on Malay folklore and is extremely interesting. It is entertaining to note that the ideas on magic and witchcraft current in Malay are similar to many which can be found in the folklore of the Occident. Bile is much prized by Malayans as a medicine. Roger of Hoveden, informs us that, in 1191, King Richard I. ordered most of those captured at the siege of Acre to be put to death.

"5000 were slain and disembowelled by the Christians who found much gold and silver in their entrails, while they preserved their gall for medicine."

Jin and other spirits, according to Malay legends precede man in creation:—

"The Creator determined to make man, and for that purpose He took some clay from the earth and fashioned it into the figure of a man. Then He took the spirit of life to endow this body with vitality and placed the spirit on the head of the figure. But the spirit was strong, and the body being only clay, could not hold it and was reft in pieces and scattered in the air. These fragments of the first great Failure are the spirits of earth and of sea and of air. The Creator then formed another clay figure but into this one he wrought some iron, so that when it received the vital spark it withstood the strain and became man."

Veritably these were men of blood and iron.

THE LANCET.

LONDON: SATURDAY, MARCH 16, 1929.

NUTRITION IN THE COALFIELDS.

THE impression produced by the latest official Report [1] on conditions in the coalfields will depend very much upon the mind and temperament of the reader. Those seeking reassurance will read with easy conviction that there is no increase in the epidemic death-rate, the death-rate from tuberculosis, or the infantile death-rate, and will reflect that any serious state of malnutrition must early show itself in an increase in some or all of these. Others may be less easily satisfied and may be led to wonder whether the latent period between malnutrition and the ultimate detriment to life may not be a long—even a very long—one, though the effect may be none the less inevitable. Conditions of malnutrition, either qualitative or quantitative, have to be very severe before they imminently endanger life, particularly where the health services are still in operation. Thus, to take as an extreme case of qualitative malnutrition the 150 cases of hunger-osteomalacia ("adult rickets") studied as out-patients by HUME and NIRENSTEIN [2] in Vienna during the food-shortage of 1920, none was ever known to be lost from the series by death, and as far as any evidence was to be found in the vital statistics that batch of terribly suffering humanity might never have existed.

"Rickets does not kill," it has always been said, and rickets is the only definite disease of qualitative malnutrition which seems likely to be a serious menace in the distressed areas. In this latest Report we are told that it is present in increased degree in certain of the regions investigated. It is not stated how the diagnosis was made, but presumably it was a clinical one based on visible or palpable deformities, and it must be borne in mind that such a diagnosis is bound to overlook many less severe cases in which the calcium balance is actually negative and the disease would be clearly shown by radiographic examination. Though we may say that "rickets does not kill," we should be extremely loth to say that any child which has had rickets will afterwards be exactly the same as if it had not had rickets—apart from the needless suffering and economic waste. The Report states that the welfare centres are dealing with the disease as soon as it appears among those who attend, but it is much to be desired that some special effort should be made to reach all children with a reliable cod-liver oil and all mothers with instruction on the importance of exposing their children to every bit of available sunshine, and so to make good as far as possible, by other than dietetic means, this qualitative deficiency in the food, if such a deficiency must continue. It is not stated whether the children affected are breast-fed babies; it is only said that they are "children in the early years of life"; so it cannot be deduced how much the child's disease may be due to the mother's nutritional failure. But the Report does go on to say that the prevailing diet is "unsuitable for the maintenance of health over any prolonged period, and especially for young children and nursing mothers." The whole account induces a profound misgiving that the supply of vitamin D, even to the adult population, may be insufficient. In view of these latest revelations, greater stress should perhaps be laid upon this particular need than was done in our columns a few weeks ago.[3] The margarine used should be exclusively one to which the vitamins A and D have been added, and fat fish should be particularly commended. Skimmed milk will supply calcium and other salts, and is a great deal better than no milk at all. It is, however, extremely hard to find cheap articles of diet which will supply vitamin D. Adults, besides children, should make use of the sunshine when it comes, and cod-liver oil should be available for mothers as well as children.

When we turn to the question of quantitative insufficiency, the Report expresses doubt also about the caloric value of the diet. Without accurate measurements of food consumed and of the height and weight of the affected population, this must be a difficult matter to decide, and where so many psychological factors exist to promote depression, the outlook of the people cannot be taken as any index of their degree of under-nutrition. It is probably outside the scope of this Report to make recommendations concerning the machinery by which the adequate qualitative and quantitative nutrition of these poor people should be secured and the Commissioners pass on to deal with political considerations where medical comment would not be relevant.

CONGENITAL DISLOCATION OF THE HIP.

CONGENITAL dislocation of the hip is relatively rare in this country. LE DAMANY estimates that there are at least 200,000 cases living in France, and in Brittany the proportion of cases to the general population is still higher. In the north of Italy also the lesion is very common; at least 1000 patients are treated annually at Milan and Bologna. We lack statistics as to its prevalence in countries other than those mentioned. In London, which probably draws cases from a population of at least ten millions, probably not more than one hundred new cases are seen annually. We cannot tell why there should be this remarkable contrast in liability to this dislocation between the inhabitants of different European countries, or why the Celtic Breton and the Lombard Italian should share the same unfortunate prominence. The sex incidence of the defect is also unexplained, for no satisfactory theory has been formulated to account for the fact that 85 per cent. of cases are found in female infants.

It is now generally accepted that the deformity is due to a developmental defect of the pelvis, which may give rise to subluxation or even luxation before birth, or may produce deformity only in postnatal life. The nature of this defect and of the progressive secondary changes which occur when the femur remains displaced form the subject of the greater part of Mr. H. A. T. FAIRBANK'S Lady Jones lecture delivered recently in the University of Liverpool. Its concluding paragraphs deal with problems of treatment by means of open reduction considered in the light of research into the anatomy of the joint. Mr. FAIRBANK bases his observations on a study not only of museum specimens and radiograms but upon facts noted during exposure of the parts in the course of operations, upon the "pathology of the living," as the

[3] THE LANCET, Jan. 5th, p. 28.

President of the Royal College of Surgeons of England has happily called this method of study of morbid anatomy. As Mr. FAIRBANK points out, the primary fault in all cases appears to be the poor development of the upper margin of the acetabulum, a defect which hinders normal function even after successful reposition of the head of the femur. Only very slowly can the defect be made good, if indeed it can ever be completely corrected. All other changes are of secondary import. That the malformation involves not only the cotyloid ligament, but also the cartilaginous margin and the bone even when dislocation is not yet complete, is clearly shown in two fœtuses described by LOCKWOOD. After birth, and when the femur has been used, usually some sort of false acetabulum is formed which is shallow and incapable of retaining the head of the bone in position. In time this false socket may show arthritic changes, to which may be due much of the pain to which adults suffering from unreduced dislocations are liable. Mr. FAIRBANK draws especial attention to the condition of the ischium, which, he thinks, has hitherto not received the attention it deserves. This bone shows more changes than any other part of the pelvis except the acetabulum itself, of which it forms part. It often displays facets and ridges; the facets may have articulated (if such a term is applicable) with a facet on the lesser trochanter of the femur, while the ridges are probably due to the attachment of a much hypertrophied ischio-capsular ligament which, as will be seen later, plays an important part in the partial stabilisation of the luxated femur. The altered joint cavity overlaps the front part of this surface. The attachments of the distended and, in most cases, thickened capsule are very different from those of a normal joint, especially as regards their extent on the pelvis. The changes in the femur and those of the acetabulum are due partly to loss of the normal reaction and stimulus to growth furnished by pressure and friction between the two; in the femur the ossific centre in the head is late in making its appearance, and when visible in a radiogram it is smaller than that of the normal head. Abnormal pressure against the pelvis distorts its external form so that it is commonly wedge-shaped, and sometimes conical. As to the neck, Mr. FAIRBANK records the appearance of coxa vara in only nine out of 32 cases. One would hardly expect marked coxa vara when the bone is not exposed to superincumbent weight upon its head. Antetorsion of the neck has been much talked of, and has been regarded as one cause of relapse, but Mr. FAIRBANK has not found it often or in great degree.

How the weight of the body is transmitted from the pelvis to the femur in an ambulant case of dislocation of the hip has been much discussed. In the absence of the fulcrum or pivot of the normal pelvi-femoral articulation, there are only muscles and ligaments to prevent the upper end of the femur ascending to an indefinite extent. Yet although there may be a certain amount of so-called "telescopic" movement, it early becomes limited and ceases to increase. Mr. FAIRBANK shows that practically all the muscles attached to the upper end of the femur take part in the task of fixing and steadying it, while they are powerfully aided by some parts of the capsule, and particularly by the ischio-capsular band, already referred to, which forms a sling across the neck of the femur, whereon it often leaves marks of its pressure. Ascent of the upper end of the thigh-bone must obviously reduce the length of the limb as measured from the pelvis, but it is a curious fact that the limb itself, measured from the great trochanter, may be longer than its normal fellow. Mr. FAIRBANK refers to a case where, ten years after reduction of a congenital dislocation, the affected limb was three-quarters of an inch longer than the sound one; but in many cases the femur is shorter than normal. The changes in the capsule are well known. The hour-glass contraction and the thickening have been observed by surgeons in many open operations, and the contraction has been long recognised as one of the obstacles against securing a stable reduction by means of manipulation. It may be so great that, with the aid of adhesions, it serves actually to divide the cavity of the capsule into two compartments. The tendon of the ilio-psoas muscle, which in most cases bends sharply outwards and backwards just below the anterior inferior spine of the ilium, often accentuates the hour-glass contraction and forms such an obstacle to reduction as to require division. But a distinct isthmus in the capsule has not been seen by Mr. FAIRBANK more than once in patients under the age of 3 years. He describes certain folds of synovial membrane which are of importance in considering difficulties of reposition. One of these is situated vertically at the back of the acetabulum, and another more or less horizontally at the level of the upper acetabular margin. This fold hinders reposition of the head; it disappears when weight is put upon the limb, but when the head is pushed down in attempts at reduction it becomes folded into a ridge below. The cavity of the joint, as described by Mr. FAIRBANK, consists of three portions, one corresponding to the old acetabulum, another over the anterior and upper part of the retro-acetabular bone, and separated from the first by a vertical fold, and a third, still higher, corresponding to and enclosing the displaced head of the femur. All the pelvi-femoral muscles are adversely affected by the dislocation. The direction of their tendons is altered and their points of insertion have an abnormal mobility when the acetabular fulcrum is absent. Some of them find their origins from the bone reduced in area. Mr. FAIRBANK discusses each muscle at some length, and shows how the three levers on which the muscles act are lengthened or shortened by the displacement of the femoral head. It seems clear that in the absence of the fixed centre of angular movement in the acetabulum nearly all the muscles concerned must be contracting in the act of walking, in order as much as possible to fix the head. During this process there must be a good deal of waste in the form of "lost motion" or "back lash," as the mechanics call it. Pain in the young is probably due to muscular fatigue from this overaction, though in the old it is often attributable to arthritis.

On the question of treatment Mr. FAIRBANK is judiciously conservative. He deprecates the tendency of surgeons in America, and in a less degree here, to resort to open operation with increased frequency. Manipulative reduction gives the best results in young children, and if it is done before the age of 3 years, or better still before the age of 2, a permanent cure may be anticipated in a very large percentage of cases. When considering open reduction, the surgeon must remember that many patients lead tolerable lives with unreduced hips. The deformity is not dangerous to life and does not justify desperate measures. As to relapses, these are often due to want of outgrowth of the upper margin or shelf of the acetabulum, for which condition open operation and bone grafting is advisable. Open operation is also useful in patients of reasonable age whose hips are irreducible by manipulation. Attempts at reduction

after the age of 9 for a unilateral and 6 for a bilateral case are of very doubtful value. For old arthritic cases arthrodesis in an artificial acetabulum is likely to give the best result. In bilateral cases, of course, only one hip must be thus fixed.

NOISE AND ANNOYANCE.

A LARGE proportion of the ills which afflict the community result, directly or indirectly, from the development of a mechanical civilisation. Congestion in large towns has led to lack of accessory nutritional factors, exercise, sunlight, and fresh air; the use of mechanical transport has been the cause of hurry, anxiety, and to a certain extent of stagnation. It is only recently, however, that any public attention has been directed to noise as a social evil. We have grown up without noticing its gradual increase, but anyone who pauses to listen to the hubbub of a London street at midday will realise how noisy civilisation has become. Lorries crash and rattle; motor-cars constantly sound electrical alarms; motor-cycles bark; hawkers cry; trains thunder beneath and aeroplanes roar above; and the road-mender's pneumatic chisel and its brother the steel-worker's rivetter complete the pandemonium.

It is probable that most city dwellers find noise an intermittent nuisance, but several high authorities have now declared that it is a definite menace to the public health, resulting in loss of efficiency and energy. The British Medical Association at its last annual meeting passed a resolution in favour of legislation empowering local authorities to suppress unnecessary din, and submitted to the Minister of Health a long memorandum on the effect of noise. The Minister also received at the end of last year a deputation, including several eminent mental specialists, neurologists, and physicians, from the People's League of Health, requesting him to promote legislation to reduce noise. Dr. Dan McKenzie, in his third Chadwick lecture, delivered on Feb. 21st, dealt with the same subject and suggested administrative remedies The effect of noise is considered on the healthy citizen, the ailing citizen, and the industrial worker. The general effect on the nervous system was summed up by Prof. G. Robertson in his speech to the Minister, and his view is supported by other specialists. "The first effect," he said, "is one of disturbance, of excitation, and of irritation. . . . It is impossible to measure these mental states with scientific accuracy or to weigh them exactly, but that they exist no one doubts. They have consequences of many kinds on conduct. They cause loss of temper, they play a part in quarrels, and they prevent deep and sustained thinking." Noise, he continued, might prevent a person from going to sleep, might break and interrupt his sleep, might make his sleep disturbed and unrefreshing, or might produce insomnia. Dr. Matthew Ray dwelt on its bad effect on the mentality of children, and Mr. E. B. Turner, speaking as a general practitioner of long experience, said that he had watched the effect of the irruption of a constant stream of noisy traffic into a previously quiet residential district; the inhabitants, who before had been healthy, developed numerous disorders. Sir Maurice Craig said that he had been impressed for many years by the increasing number of persons whose health had suffered from noises in the streets of London. Dr. Ray also pointed out the extent to which street noises delayed the recovery of hospital patients. Speaking of industrial noise, Sir Thomas Oliver contended that it caused structural changes in the organ of hearing and functional derangement of the nervous system. Holders-up and rivetters nearly all had their hearing affected in a few years, and suffered from impaired health.

Various remedies have been suggested for this evil. The deputation recommended that noise should be placed among the nuisances with which a sanitary authority is empowered to deal under Sections 91–112 of the Public Health Act, 1875. It probably also had in mind the possibility of legislation empowering the Ministers of Health and Transport to frame ad hoc regulations for the suppression of particular noises. Mr. Turner suggested the enforcement of zones of silence round hospitals; the placing of white lines across the openings of side roads into main roads to obviate hooting; limitation of weight and bulk of goods carried by road, and the speed and hours of work of lorries; pneumatic tyres on all lorries; the prohibition of sale of motor-cycles without effective silencers, and strict enforcement of the law on silencers; and the by-passing of as many country towns as possible. Dr. Dan McKenzie suggested that zones of silence during hours of silence should be enforced by the police; that streets in front of schools, colleges, hospitals, and nursing homes should be rubber-paved; that the size, weight, and speed of motor-lorries should be reduced, and that heavy goods should all go by rail. The British Medical Association, in addition to the nuisances mentioned, included the cries of street-vendors, the barking of dogs, and the careless handling of milk cans. They suggested that pneumatic drills should be forbidden altogether in proximity to occupied dwelling-houses at night, and that some educative campaign should be started to reform those who "race" their engines while shouting noisy good-byes after parties in the small hours.

Unfortunately, the remedy is not clear. The Minister of Health expressed serious doubt whether any clause concerning noise could be introduced into the Public Health Act as it stood, but manifested a desire for more scientific data; and this would probably be the attitude of the legislature towards any ad hoc measure. Many citizens might well hesitate to add to the already formidable extra-legal powers possessed by Government departments without overwhelming necessity. Again, as the Minister observed, many authorities doubt whether noise in industry interferes with the health of the workers to the extent suggested, and Dr. McKenzie, at the close of his lecture, admitted that a large proportion of the noises which troubled hospital patients originated inside the hospital. These public pronouncements have undoubtedly expressed a need, but that need will best be served in the immediate future by the patient accumulation of trustworthy evidence upon which legislative reforms would follow. The views expressed by the medical authorities who took part in the deputation to the Minister of Health were perhaps more emphatic than scientific; the effect of noise in producing nervous illness among factory workers, for example, should be capable of more exact proof than has been provided. One direction for exact investigation was indicated in our own columns last week by Prof. Swale Vincent and Mr. J. H. Thompson who showed the effect of agreeable sounds upon blood pressure in the human subject. Disagreeable sounds may well have a pressor effort which could be determined. Mr. Neville Chamberlain, in his reply, pointed out that he did not recognise in his own case the alarming effects depicted by one of the deputation, and there are certainly many who, like him, are unaffected by noises that may be

intolerable torture to less fortunate or more nervous people. Yet the fact that large numbers of people, whether nervous or not, undoubtedly suffer intensely from noise is sufficient for all reasonable persons to support measures to diminish this nuisance. Meanwhile, however, there exists another and perhaps a more effective approach to the problem. So much of the harm is done by individual thoughtlessness—the noisy theatre-party, the loose tailboard, the unnecessary klaxon, for example—that it seems reasonable to hope that real reform could be brought about by the same methods which have caused a marked reduction in the amount of litter and vandalism in our parks and public places.

Annotations.

"Ne quid nimis."

LOCAL GOVERNMENT BILL.

OUR readers will have followed in the daily press, and at greater length in our own columns, the proceedings in the House of Lords while this important measure has been under debate. Last week Lord Onslow offered to introduce a clause impressing upon local authorities the desirability of their fullest coöperation with the voluntary hospitals, the offer being in reply to Lord Reading's criticism of the lack in the Bill of such provision. As a result a clause was agreed which was so far satisfactory that Lord Dawson withdrew his intended amendment, the first part of which was thereby met, relying on Lord Onslow's offer to amend the new clause on the Report stage of the Bill so as to ensure consultation between the public assistance committees and representatives of the local medical practitioners of the area. The feeling of the medical profession will certainly be in favour of any plan which will bring private practitioners, individual or consultant, into working coöperation with the public health services, and it is difficult to see upon what grounds so important a provision can be refused, or why anything but general profit should be expected from it. An account of the debate will be found on page 571 of this issue of THE LANCET.

INJURIES IN WORKSHOPS.

THE war and the decade succeeding it has seen many far-reaching changes in the practice and conduct of industry. Not least important of these is the greater attention paid to the human factor, and among other aspects of industrial welfare work the prevention and treatment of accidents is one that has naturally received a good deal of consideration. This particular problem was brought into much prominence during the war, when the speeding up of production was partly responsible for an increased number of industrial accidents. By the Police, Factories, &c. (Miscellaneous Provisions) Act, 1916, the Home Secretary was empowered to make statutory orders regarding the provision of first aid and ambulance arrangements in factories. In 1919, by which time the obligatory provision of these orders had been applied to a comparatively small number of industrial processes, the Home Office issued a small pamphlet, for the guidance of employers and others, on the general principles of first-aid and ambulance arrangements. Sections on first-aid boxes and their use, ambulance rooms and their equipment, the removal of injured persons and the organisation and training of first-aid personnel were followed by appendices and plates; the whole forming a concise and useful guide to the subject from the point of view of those to whom it was addressed. In 1923 the mass of statutory orders had reached the stage where simplification was desirable, and by the Workmen's Compensation Act of that year (which was not repealed in respect of first-aid matters by the Workmen's Compensation Act, 1925) the whole of British industry was brought into line, and the universal provision of first-aid arrangements was made obligatory in all factories. Voluntary societies and the private efforts of individual firms have done much to forward the work of caring for the injured at work, so that to-day most industrial plants are fitted to deal adequately with all those minor accidents which have so unhappy a knack of having unfortunate sequelæ as a result of sepsis or neglect. Official action during this time has been consistently helpful, and the changes brought about by the 1923 Act were effected without friction largely owing to the conciliatory and helpful advice given in all cases by the Home Office. After ten years of progress and change the Home Office pamphlet which proved so useful at its first appearance has passed to a second edition,[1] and while it retains all its former virtues some of these have become somewhat dulled by the passage of time. Change for the sake of change is undesirable, but the complete re-drafting of such a publication as the one under review tends to maintain interest, whereas its mere reprinting with a few minor additions and complete with the original war-time photographs may induce a sense of stagnation rather than progress. The 1919 edition urged the necessity for a more extended course of first-aid training for welfare workers, and suggested that the courses might have to be revised in the light of this need. The paragraph is reprinted in the new edition, but no indication is given of what has been done during the preceding decade to supply a need which, owing to the extended scope of the work called for by the Workmen's Compensation Act, 1923, has become vastly more important than it was ten years ago. The rest of the booklet is accurate, concise, and helpful to the layman confronted with the task of complying with the regulations or making a voluntary effort to provide facilities in excess of those required by law; but anyone who compared the two editions might be pardoned for wondering whether any official notice had been taken of the mass of voluntary effort made by progressive firms in the past few years, while an inquirer making his debut in this field might well ask whether the photographs really represent the last word in design. If he deduced from this that the rest of the book was a little out of date, he would be wrong; but attention to details of this kind sometimes makes the difference between interest and apathy.

PARASITIC PROBLEMS IN THE LESSER ANTILLES.

THE oldest of Britain's surviving colonies and once the most highly prized of all, the Sugar or Caribbee Islands, now have sunk into comparative oblivion. Many factors have been responsible for this: the opening up of the new and larger lands elsewhere, the abolition of cheap slave labour, the fall in the price of sugar, the lessening demand for the long-stranded sea-island cotton used in lace-making, are some of the more obvious. Yet although they are now not much in the public eye unless some devastating hurricane or some volcanic outburst brings them forcibly into the daily papers, they present important problems to the hygienist. Some of these—more particularly those caused by the animal parasites—were considered by Dr. T. W. M. Cameron in a paper read last week before the Tropical Diseases Section of the Royal Society of Medicine. The most widespread and serious problem is malaria, which is common on most of the islands. Barbados, once free from this disease, was the seat of a serious epidemic in 1927, which has not yet been brought under control; and the only islands now free from the parasite appear to be Montserrat and St. Kitts.

[1] First Aid and Ambulance for Factories and Workshops Welfare. Pamphlet No. 4. 2nd edition. Home Office. H.M. Stationery Office. 1929. 4*d*.

Filariasis, another mosquito-borne disease, is still rampant in many of the islands, although in general its importance seems to be steadily declining. "Barbados leg," as elephantiasis once was called, is now comparatively rare in that island, and even in St. Kitts and Antigua, which once were strongholds of the disease, there has been a very considerable decrease in its incidence during the past 20 years. The majority of the important diseases, however, are fæces-borne; enteric and dysentery, diarrhœa both in infants and children, and helminthiasis are the commonest of these. Enteric and dysentery are not so universal as they used to be, but helminthic parasites are still very common. Hookworms are found in all the islands but are especially common in the southern groups. In Barbados, with two kinds of soil—clay and chalk—they are widespread on the first and rare on the second; in Antigua where chalk, clay, and volcanic soils are found, there is a light infection on the chalk, medium on the clay, and heavy on the volcanic portions. In all districts soil pollution is universal and heavy, and light infestations are due to natural causes, not to man's activities. The round worm, *Ascaris lumbricoides*, is even more common and about 60 per cent. of the inhabitants are infected. These two parasites cause a great amount of debility and are very important economic factors in the prosperity of the islands.

Schistosomiasis has not the same general spread as the truly intestinal parasites, and is confined to St. Kitts, Antigua, and St. Lucia among the British islands. The parasite found in these islands and throughout the tropical parts of the New World is *Schistosoma mansoni*. It was first reported by Sir Patrick Manson from Antigua in 1902, but there is reason to suppose that the patient acquired his infection in St. Kitts. The parasite, like all the others, originally came from Africa, probably with the negro. In St. Kitts, however, for over a hundred years African monkeys have roamed the forests and plagued the planters; Dr. Cameron found that in addition to being an economic nuisance, they were also harbouring *Schistosoma mansoni* and were consequently likely to prove a serious factor in any schemes for the eradication of the disease. Therapeutic measures, which have been successfully used against this parasite in man, could in theory eradicate it if all human carriers were treated and cured and if no reservoir existed to reinfect the snails. But a wild monkey cannot be treated and so eradication must necessarily, in St. Kitts at least, lie in attacks on the immediate hosts which live in considerable numbers in the few streams in the island. Among the minor horrors of the West Indies are insect pests of all sorts; the domestic flies, particularly evident on Sundays when the shops are closed; mosquitoes, which bite in relays throughout the 24 hours; chigger fleas, which burrow into the skin of the toes; Jack Spaniards, large wasps which can sting most ferociously; bêtes rouges, harvest mites which climb up the grass on to the limbs and where the clothing fits tightly, enter the skin—these and many others plague the life of the stranger. In a few islands poisonous snakes still exist, while in Trinidad there lives a species of blood-sucking bat which, while it does little permanent damage, is a considerable source of annoyance to man and beast alike. The major problems of these islands, however, can be solved only by drainage and fæces disposal schemes—and above all by education. The negro has still to acquire the latrine habit; when he has done this the high degree of parasitism will be enormously reduced. Venereal disease, another major scourge, can only be eliminated by an enlightened and educated public opinion. Malaria and filariasis depend on mosquito eradication in which drainage plays an important part. But all these hygienic measures depend on material prosperity and a new outlook on the part of the peasant. The material prospects of many of the islands are not too good, but a trade in tropical products and a multitude of visitors to what might easily be ideal health resorts would help to counteract the adverse effects of beet and artificial silk on the cane-sugar and cotton industries. The outlook of the negro is another matter, however, which will only be altered after much constant endeavour. Nevertheless, as Dr. Andrew Balfour pointed out in the discussion, considerable advances have been made within the last 30 years and more than would seem possible at the moment may yet be accomplished. These islands are among the beauty spots of the earth. Their soil is fertile and their climate, though tropical, is tempered by the trade winds from the Atlantic. Any effort to make them agreeable health resorts would probably be well repaid.

SURGERY IN THE DIABETIC.

In prolonging the lives of diabetics insulin has increased the number of those who develop surgical complications or coexistent diseases needing surgical treatment. J. A. Reed[1] finds that the surgical mortality-rate has been reduced to one-third of what it was before the use of insulin, but, of course, these patients still run a greater operative risk than normal people. For successful treatment the first essential is close coöperation between the physician and surgeon, both before and after operation. The aim of treatment is to maintain the blood-sugar at its normal level, to promote storage of glycogen by the liver, to overcome ketosis, and to give a sufficient amount of fluid. To accomplish this Reed is accustomed to give a diet containing 100 g. of carbohydrate, the same amount of fat, and 1 g. of protein per kg. of body-weight, with enough insulin to abolish ketosis and bring the blood-sugar to normal level. When this has been done the operation is performed, preferably two hours after the usual breakfast, given in fluid form. In his opinion the anæsthetic of choice is ethylene and nitrous oxide, with ether in cases where greater relaxation is required. After operation the patient should return as soon as possible to his previous diet, while starvation is to be avoided at all costs. In the treatment of diabetic gangrene, Reed again emphasises the importance of early consultation with the surgeon, and points out that to-day infection and gangrene are greater enemies to the surgical diabetic than acidosis and coma. Focal sepsis and arteriosclerosis are the two most important predisposing causes of gangrene, and uncleanliness of the feet is a factor which should not be forgotten. In a paper on diabetic gangrene, B. C. McMahon, Rudolph Scharf, and W. M. Bartlett[2] say that although cases of dry gangrene often recover entirely with adequate medical treatment, gangrene which is tending to spread, or is associated with severe toxæmia or septicæmia, or occurs in a patient whose diabetes cannot be controlled with insulin and diet, should be treated as a surgical emergency. In their series of 19 cases, ten healed by primary and six by secondary union, while one failed to heal in six months. In one of the fatal cases death followed reamputation for secondary gangrene, and in the other it was due to septicæmia. These writers emphasise the importance of radical surgical treatment, bearing in mind the risk of possible reamputation, and for gangrene below the knee they prefer the Stokes-Gritti amputation, both as regards healing capabilities and the giving of a good weight-bearing stump.

NEW VIEWS ON RHEUMATISM IN CHILDHOOD.

One result of the renewed interest in rheumatism is that work in other parts of the world is being studied with more care in this country. As far as rheumatism in the child is concerned many observers think that the disease is much more prevalent here than elsewhere, but it would be rash to conclude from this that knowledge of the disease is confined to these islands. Work in America has attracted attention to the possibility of rheumatism being in the nature of an allergic

[1] Surg., Gyn., and Obst., Jan. 1929, p. 44.
[2] Ibid., p. 125.

phenomenon, and in a paper [1] recently published in Germany Prof. E. Stettner discusses articular rheumatism in children with the same theory in view. Starting with the universally accepted idea that acute polyarthritis is the result of an infection he points out that there must be some other factor present—namely, the reaction of the body to the invading noxious agent. Most authorities ascribe polyarthritis to the presence of some focus of sepsis, but no very clear idea of the nature of the "poisoning" is offered, nor is it explained why various serous membranes should be picked out for disorder. Moreover, infection by the common pyogenic organisms may occur at any age; yet infants and very young children for the most part escape acute rheumatic fever. Stettner believes that this is because the patient must first develop an increased sensitiveness to infection, and that when this is present further infection, even if slight, will produce an allergic polyarthritis. A latent period is necessary during which there are certain chemical changes, and as a result the allergic state develops along with local anaphylactic phenomena in the synovial membranes and endocardium. When the "rheumatic reaction" has thus taken place other factors, such as cold and environmental conditions, may be exciting causes of the acute attack. The influence of heredity has also to be remembered, and in a group of 50 cases specially studied by Stettner for the purposes of his paper there were 20 in which the parents or grandparents had suffered from rheumatism, and 13 in which a history was given of eczema, asthma, and other phenomena of the hypersensitive state. The clinical studies of the cases of polyarthritis under observation brought out other evidence against the idea of a simple infective process. There were many examples of derangement of the capillary blood-vessels, such as peliosis and hæmorrhages from the gastro-intestinal and renal tracts. The blood picture also was not like that of ordinary sepsis; there was only a slight leucocytosis, with no "shift to the left" in the Arneth count and no disappearance of the eosinophils—all three points being opposite to what would be expected in septic infection. Stettner concludes that, in addition to the exogenous factor in rheumatic diseases, there is an altered state of the organism as a whole. Polyarthritis is, of course, seen in other definite diseases such as dysentery or serum sickness, where the type of reaction of the synovial membrane is similar to that of acute articular rheumatism, and such joint changes appear to be part of an allergic phenomenon. The unsatisfactory feature of the hypothesis is the fact that acute joint changes in the rheumatic fever of children in this country are nowadays very rare and the slow insidious onset of rheumatic carditis, often without fever, does not fit in well with the picture of the allergic state presented by Prof. Stettner.

VACCINES IN THE TREATMENT OF ACUTE PULMONARY DISEASE.

A QUARTER of a century ago the medical student looked forward eagerly to the day when pills and potions would give place to vaccines and sera in the treatment of acute and chronic infections. Lectures on pharmacology and demonstrations in the apothecary's shop were of service only in so far as they might help him on the day of trial at the examination hall. In the years to come the laboratory would displace the dispensary as the armoury from which he would draw his weapons. To those instructed by Metchnikoff and Wright the control of infection would become almost as simple as the heart could desire.

In a useful summary of recent French work on vaccine therapy Dr. Georges Rosenthal [2] recalls the familiar argument. An invading army of microbes, assisted by their appropriate toxins, is opposed by a mobilisation of leucocytes supported by the opsonins, agglutinins, and precipitins of the plasma. The issue of the struggle depends on the ability of the leucocytes to engulf and digest the offending micro-organisms, a struggle in which the vital energy of the leucocyte is the all-important factor. If this energy is insufficient the capacity of the white cells may be strengthened by training; the stimulus of pathogenic organisms which have been deprived of offensive power by death or enfeeblement may be used to evoke the latent possibilities of their defence. As Dr. Rosenthal points out, this theory unites the specific and general conceptions of vaccine therapy. It is simple and applicable, and though the results of its application have been disappointing, our disappointment may possibly spring not so much from the inefficacy of vaccines as from generalisations based on insufficient experience. Our French colleagues, who have made a more extended trial of this method, still maintain that it is valuable, and go so far as to say that those who refuse to use vaccines in acute pulmonary disease are guilty of criminal neglect. In the absence of any satisfactory alternative method of treatment the opinion of so many continental physicians should not be ignored.

Theoretically, in applying vaccine therapy we should determine the exact bacterial formula and prepare a vaccine corresponding to a recognised pathological grouping. The struggle against microbe A will be best maintained by a leucocyte trained to engulf microbe A. But the leucocyte stimulated by microbe B will be a better fighter against A than one which has not been so stimulated, especially if A and B belong to allied groups. This explains the benefits attributable to group and non-specific vaccines. An exact formula is difficult to establish and autogenous vaccines involve loss of time in preparation and considerable expense. For practical purposes, therefore, says Dr. Rosenthal, the determination of the principal organisms concerned, and the choice of an appropriate stock vaccine, will suffice. In deciding what is the nature of a pulmonary infection lung puncture may be essential in children whose sputum is swallowed, but in the adult culture from expectorated material may serve. Cultures from the nasopharynx have also been employed on the assumption that all organisms found in broncho-pneumonic areas are also to be found in the upper respiratory tract. Thus L. Duchon holds that whatever organisms may have been responsible for the onset of a broncho-pneumonic attack the terminal fatal aggravation is often due to a descending infection, and he therefore includes the disintegrated Klebs-Löffler bacillus in his vaccine. Unfortunately, Dr. Rosenthal points out, there is a wide divergence of opinion about the best composition of vaccines. Thus Bruschettini recommends an emulsion prepared from intrapleural exudate provoked by the injection of streptococci, staphylococci, pneumococci, and *Bacillus coli*, a method first used against secondary infection in pulmonary tuberculosis. Duchon uses solutions of streptococci exposed to the disintegrating action of *B. pyocyaneus* after filtration forming "lysats vaccins" which contain living antigens. A. Dufort and P. Sédallion maintain that streptococci have no power to provoke the formation of antibodies, while Duchon and A. Mauté submit that the streptococcus is alone responsible for their production. A. Ranque and C. Senès lay chief stress on the importance of the pneumococcus and consider that streptococci only give rise to antibodies if grown in media with ascitic fluid. Thiercelin advises an emulsion of enterococci given by the mouth. Thus the diversity of opinions expressed seems to be only limited by the number of investigators. The best method of introducing the vaccine has also been a matter of dispute, the hypodermic, intramuscular, oral, intravenous, nasal, intratracheal, and transpulmonary routes having all been employed. In transpulmonary inoculation a fine needle with multiple openings is used for the injection of an aqueous isotonic solution, and this is the method which Rosenthal regards

[1] Deut. med. Woch., Feb. 15th, 1929, p. 264.
[2] Arch. med.-chir. de l'appar. resp., 1928, iii., p. 209.

as the best for infants. In adults lipo-vaccines (e.g., oily suspensions of streptococci or pneumococci) may be administered through a fine curved cannula inserted into the trachea, the dosage being similar to that recommended for hypodermic administration.

Dr. Rosenthal concludes that while vaccine therapy has long passed the experimental stage in the treatment of broncho-pneumonia, the problem of the best composition of vaccines has yet to be solved, and this must involve much further work on the part played by various organisms in pulmonary inflammations. Meanwhile he maintains that ignorance and sloth alone are responsible for the prevalent neglect of therapeutic measures of the highest value.

THE BIOLOGICAL ESTIMATION OF TOXICITY.

THE assumption that the efficacy of organic arsenical preparations varies directly with their toxicity has its origin in the circumstances which followed the production in this country, during and after the war, of batches of novarsenobenzene (neosalvarsan). It will be remembered that British manufacturers found the details set out in the patent specifications to be inadequate, and had to rely on the ingenuity of their technical advisers to supplement them. At the request of the Board of Trade the Medical Research Council devised biological tests to ensure that the products on the market were suitable for clinical use. After various experiments, an empirical basis for testing [1] was found. Only such batches were passed as were tolerated by at least four out of five mice in an intravenous dose of 0·3 mg. per gramme of body-weight. Using this method it was discovered that the preparations submitted for testing fell into two well-marked groups. One group resembled the original German product in appearance, solubility, lack of stability when exposed to air, and toxicity. The other group was much more soluble and stable and far less toxic, and for all these reasons achieved a popularity with practitioners which became disturbing when reports began to come in from reliable sources criticising the potency of the material. A test for therapeutic efficacy then became necessary and was adapted from one developed in America. The substances were injected into the veins of mice experimentally infected with the trypanosome *T. equiperdum*, the minimum curative dose being arbitrarily fixed as that which caused disappearance of the organisms from the circulating blood at a period of 72 hours after the injection. By this means it was found that the more stable, less toxic batches of material were inferior in therapeutic value to the older preparations. Clinical trials on syphilitic patients with surface lesions confirmed the results obtained on mice. The manufacturers were fortunately able to remedy the defect when their attention was called to it, but the variations made obvious the desirability, which has since been confirmed, of imposing an official control of potency as well as of freedom from toxicity. Meanwhile the creation of internationally valid standards under the direction of the Health Organisation of the League of Nations has ensured that a substance of uniform strength and toxicity is available for comparison. The International Conference on Biological Standards, which met in Geneva in September, 1925, laid down tests for potency and toxicity, but was unable to prescribe the limits of permissible variation from normal values, since evidence as to the accuracy with which either property could be estimated was lacking.

An attempt to furnish this evidence as regards the toxicity of one substance, novarsenobenzene, has now been made, under the general direction of Dr. H. H. Dale, by a group of workers [2] in the Department of Biological Standards of the National Institute of Medical Research. The task has been found unexpectedly complex. The determination as to what shall be regarded as a lethal dose is the first step—shall it be one which kills any animal, every animal, or some intermediate proportion? Again, even when a characteristic curve relating doses of the standard preparation to death-rate in mice had been determined, how could a test be devised that would discriminate sharply between those samples which conformed to the standard within reasonable limits—say, 20 per cent.—and those whose toxicity was still higher? The work was further complicated not only by the suspicion of variations in sensitiveness between individual animals, but by the possibility of variations due to age, strain, parentage, dietetic history, sexual development, seasonal changes, and sex. Not even weight could be excluded, though the test dosage given was in milligrammes per gramme weight of the experimental animals, for it was discovered that small immature mice had more resistance than mature ones, whose resistance diminished only up to a certain age.

It was found eventually that errors could be to some extent eliminated by choosing mice within narrow limits of body-weight—between 18 and 20 g.—of the same strain and kept and fed under similar conditions. These precautions having been taken, various samples were tested for toxicity against the standard preparations, and an investigation into the tests in current use in various countries was made. The British test hitherto performed is criticised as lacking sharp discrimination, since of batches 50 per cent. more toxic than the standard only two-thirds of the samples are rejected. The German test involves an inconveniently large number of mice. The Japanese test is more lenient than either, but this leniency is neutralised if, as Prof. Hata, of Tokyo, believes, the Japanese mice have a lower resistance than European strains. The official American test is on rats and not on mice. In the light of all this information the onerous task of framing an improved test was undertaken. The final demand of this new test is for a survival of at least 50 per cent. of 30 mice weighing 18 to 20 g. injected with 7·6 mg. per mouse of the sample under examination. The test is conducted in three stages, so that those samples which are practically certain of acceptance or rejection are eliminated after the preliminary test on ten mice; thus as many as 30 mice are needed only for the doubtful samples submitted to further test. Since the details of this method were worked out, the International Conference held at Frankfort in 1928 has agreed to recommend a 20 per cent. excess of toxicity as the limit of tolerance. This is a standard less rigid than was contemplated, but can be met by altering the dose given to each mouse from 7·6 mg. to 7·2 mg. Emphasis is laid on the fact that the true function of the international standard preparation is to test the sensitiveness of the mice which are being used to assess unknown samples, and to provide a basis of comparison between the effects of tests carried out on different species of animals. Finally, in a note on the need for a therapeutic test, it is recorded that one batch of material of such high toxicity that it would not have passed any test was found to have very small therapeutic activity. The conclusion is that while toxicity and efficacy may show a certain parallelism within a limited range of samples of a particular manufacture, it is still necessary to maintain independent tests for both properties in relation to a common standard.

The fact that this intricate work is concerned only with the toxicity of one preparation shows what difficulties lie in the way of a controlled pharmacology of biologicals. It has hitherto resembled the Carrollian game of croquet where flamingoes as mallets hit hedgehog balls which have been only too likely to influence the direction of motion by their own individuality. The business of eliminating or allowing for the variables is well in hand, and provided that the game is not required to be played on the old system of rules, there is no reason why

[2] Special Report Series, No. 128. Reports on Biological Standards, II. Toxicity Tests for Novarsenobenzene (Neosalvarsan). By Florence M. Durham, J. H. Gaddum, and J. E. Marchal. H.M. Stationery Office. Pp. 40. 9*d*.

it should not be organised on a plan that all nations can follow. Miss Durham and her colleagues have made a valuable contribution to this end.

STERILITY IN WOMEN.

THE haphazard methods generally employed for the relief of sterility are rapidly being replaced by scientific investigation and rational treatment. It is essential that the medical man should be able to advise his patients from accurate knowledge of the character of the operation required, the prospect of pregnancy following such an operation, and the unavoidable risk entailed. To the principals the importance of the operation depends on their desire to become parents and it is only right that a fair statement of the prospects should be laid before them. Henry Schmitz has lately made a careful survey of the literature of this subject, and though his paper contains no original work, his analysis of 118 papers is certainly worthy of notice. He points out that salpingography was first practised by W. H. Cary who described his method in 1914. After this, little seems to have been done until I. C. Rubin in 1920 published his results of tubal inflation by means of oxygen. Since then, methods of filling the tubes with opaque substances have been revived. Lipiodol, the substance now most commonly employed on account of its harmless properties, was introduced to gynæcological practice in 1925 by Sidney Forsdike who has shown that it is absorbed from the peritoneal cavity without producing any reaction. Some of the most recent work in this country is to be found in his book, "Sterility in Women," which gives a clear account of the information to be got by the intelligent use of gas for inflation of the Fallopian tubes and the radiographic evidence obtainable by the injection of lipiodol into the uterus. Schmitz finds that in 371 cases of salpingostomy reported by 13 authors, pregnancy supervened in about 8·4 per cent. He lays stress on the fact that if there is to be any hope of success the mucosa of the tube must be intact. The treatment in these 371 cases seems to include every type of plastic operation on the tube, and we suggest that when the operation consists merely of freeing adhesions and opening out intact fimbriæ, some word other than salpingostomy should be used to describe it. Forsdike thinks that the prospect of patency being maintained is poor if the operation involves more interference than this. Cases of pregnancy following resection and reimplantation of a tube into the uterus are quoted, but probably this operation is very rarely successful. Both Forsdike and Schmitz mention the occurrence of pregnancy after the grafting of the ovaries into the uterine cornua but neither gives any opinion on the value of the operation.

During the next few years further advances will no doubt be made in the investigation and treatment of sterility. It is to be hoped that accurate statistics of all cases treated and the clinical details of the operative procedure will be given, as well as a record of subsequent pregnancies.

TRAVELLING SCHOLARSHIPS.

THE Chadwick Trustees are inviting applications for two travelling scholarships of £400 a year tenable for one year to be awarded next July, one in sanitary science and the other in municipal engineering. The candidates must be British subjects between the ages of 25 and 30 who have graduated in a British university. These facts have already been announced in our columns, and it may be well to indicate that scholarships to enable students and post-graduates to obtain wider knowledge conducive to international relations in medical science are all too few, so that the opportunity presented by the Chadwick Trustees should make a wide appeal to younger members of the medical profession. The fact that the applicant is required to submit for the approval of the Trustees a scheme of study which he would be prepared to undertake and his itinerary should stimulate the applicant to the intensive study of different aspects of preventive medicine, while successful applicants will have a splendid opportunity of playing their part in helping towards that international reciprocity in medicine, the value of which, and, indeed, whose advent depends upon the clear vision and practical work of its votaries. Applications should be made by letter before March 25th to the clerk of the Chadwick Trustees, 204, Abbey House, Westminster, London, S.W. 1, stating name, qualifications, age, and proposed object of study or research accompanied by copies of testimonials and evidence of previous work undertaken or published.

THE next social evening at the Royal Society of Medicine will be held on Wednesday, March 20th, when the President and Lady Dawson will receive the guests at the Society's house in Wimpole-street. The reception will begin at 8.30 P.M., and at 9.15 Dr. Leonard Williams will give an illustrated address on Napoleon III.

THE Minister of Health of the National Government of the Republic of China, Hsueh-Tu-Pi, has invited Sir Arthur Newsholme, Dr. Louis Rajchman, Secretary of the League of Nations Health Organisation, and Dr. Victor G. Heiser, of the United States Public Health Service, to form an International Advisory Council to assist his Ministry.

WE regret to record the death of Viscount Finlay of Nairn, British member of the Permanent Court of Arbitration at The Hague, and sometime Lord Chancellor of England. The eldest son of William Finlay, F.R.C.P., of Edinburgh, he followed at first his father's profession and graduated in medicine at Edinburgh University before being called to the Bar in 1867. The viscounty descends to his only son, Sir William Finlay, judge of the High Court of Justice.

THE Thirteenth International Congress of Ophthalmology will be held at Amsterdam and The Hague from Sept. 5th to 13th. The main subjects of discussion will be the Ætiology and Non-operative Treatment of Glaucoma, the International Campaign against Trachoma, and the Diagnosis of Suprasellar Tumours, whilst among other topics to be reported on are methods of examining visual acuity, perimetry, determination of axis in astigmatism, examination of the sense of light, standardisation of rules for the examination of railway employees and other workers, and the ophthalmological study necessary for physicians and specialists. Besides the official sessions and receptions a programme has been arranged allowing for excursions and sight-seeing. The secretary of the Dutch National Committee is Prof. W. P. C. Zeeman, Wilhelminagasthuis, Amsterdam.

WOMEN'S HOSPITALS.—The erection of the new Joint Hospital for Women at Liverpool, towards the cost of which £101,000 has been subscribed, will shortly be begun.—Redlands Hospital for Women (the Glasgow Women's Private Hospital), which is staffed and managed by women, last year treated 557 patients, and is in serious need of extension.

WESTERN OPHTHALMIC HOSPITAL.—At the first annual meeting in the new premises in Broad-street, Holborn, held last week, it was stated that, the new hospital being nearly thrice the size of the old one, the cost of maintenance would be almost trebled and would amount to £20,000 a year at least. About £120,000 had been raised, but to clear off debt and provide for the increased cost of working a further £50,000 was needed. The Guild of Gratitude, formed two years ago by the out-patients, numbering 11,000 members, has collected £2500.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCLXXXIX.

THE AMBULATORY TREATMENT OF PILES.

APART from the ordinary methods of operation, two different methods of treating piles are in use: (1) injecting the pile mass with various solutions, and (2) cauterising the interior of the pile under local anæsthesia.

In employing any of the procedures which permits the patient to carry on his usual occupation without lying up or using any special precautions, certain conditions must be complied with. The method must not cause the patient anything but a minimum of discomfort, it must be at any rate reasonably efficient in its results, and above all it must be safe, so safe indeed as to be practically fool-proof. Any method, therefore, which offers the least prospect of any complication does not commend itself. Complications which are to be feared are infection of the pile at the time of treatment, with the possibility of abscess formation or, worse still, pyæmia or septicæmia, or necrosis so severe as to result in the separation of a slough with subsequent infection or secondary hæmorrhage.

The Injection of Astringent Solutions.

In order to render the first-named complication—viz., infection of the pile—as remote as possible, it is clear that a powerful antiseptic solution is to be preferred as an injecting medium to any other. It is on this score that I have never used many solutions which have been extensively, and I am sure most successfully, employed by many practitioners. I first used a 10 per cent. emulsion of phenol in liquid extract of hamamelis and water, as recommended by Mr. Dudley Wright,* and later a 20 per cent. solution of phenol as recommended originally by Mr. Swinford Edwards as long ago, I believe, as 1882. This was formerly used with great success by Mr. A. Morley, but I understand from his recent writings that he is now using a weaker solution. That a 10 or a 20 per cent. solution fulfils the first of the requirements stipulated—viz., absolute freedom from any risk of infecting the pile under treatment—is shown by the fact that though I have performed several thousand injections, I have been unable to trace a single instance of abscess formation.

As far as the second complication is concerned—that is, necrosis resulting in the formation and separation of a slough with the possibility of secondary hæmorrhage or infection, or both—I do not think that any particular solution will guarantee immunity. Necrosis may be caused by injecting any solution if the amount injected is too great. The only way of preventing it is by exercising great caution in the quantity inserted. I shall refer to this point later in describing my own technique, which I believe renders the chance of injecting too much so small as to be negligible.

The third complication to be feared—secondary hæmorrhage—I believe to be due, apart from infection, to necrosis, and the only way of preventing it is once again by exercising caution in the amount injected.

The outcome of my experience is, then, that in treating piles by injection, a solution consisting of one part of phenol, two parts of glycerine, and two parts of distilled water can be recommended with confidence. Infection seems almost impossible, and if reasonable caution is employed, sloughing and secondary hæmorrhage need not be feared. This 20 per cent. solution has proved more efficacious in shrivelling up the piles than the 10 per cent., although the 10 per cent. solution gives very good results.

**The Treatment of Hæmorrhoids, H. J. Glaisher, 1913.*

Cauterisation under Local Anæsthesia.

This method is free from the risk of initial infection, as its originators wisely employ an antiseptic solution for producing anæsthesia. The heated cautery is its own sterilising agent. I have employed the method and have found it to be painless and effective. Reports that rather severe secondary hæmorrhage may occur about the fifth day, although only exceptionally and not of alarming degree, have induced me to abandon this procedure. It may be excess of caution, but unless a patient is under continuous observation, I do not care to run even the smallest risk of any complication if any means offer themselves for its avoidance. My own preference, therefore, is for the injection method, using as a medium Mr. Swinford Edwards's solution.

The Type of Pile Susceptible to Injection Treatment.

There are three things of far greater importance from the point of view of the practitioner who is contemplating treating piles by injection than the best medium. The first is the type of pile which is susceptible to this form of treatment, the second the anatomy and mode of development of the only kind of pile which is worth so treating, and the third what period of relief he is in a position to offer a patient who asks for treatment by this method. To dispose of the first question, I am frequently asked whether injections are any good for treating external piles. External piles are composed of skin and contain few blood-vessels, and the interior consists mainly of loose fibrous tissue. Any astringent solution produces its effect, as has been shown by Dr. Cuthbert Dukes, by causing thrombosis of the vessels and aseptic fibrosis of the loose areolar tissue which forms the core of the internal pile. It is therefore obviously impossible to abolish external piles by injection. The injection causes great pain, and unless enough were inserted to produce extensive sloughing, there is no prospect of cure. Such a barbarous method of procedure could scarcely find an advocate to-day. The key to the remaining two questions is to be found in Mr. Ernest Miles's admirable paper published in *Surgery, Gynecology, and Obstetrics* (1919, xviii., 407). The following account is based largely on Mr. Miles's observations. He divides internal piles into three types—each type producing special symptoms.

The First Stage Pile is usually small and is covered by healthy pink mucous membrane and is situated entirely above the muco-cutaneous junction (Hilton's line). The interior of the pile consists of a collection of small arteries, veins, and capillaries embedded in loose areolar tissue. Unless it is of unusual size prolapse does not occur. If, however, the pile is exceptionally voluminous the lower part may prolapse through the anal orifice and become strangulated. The only symptom at this stage is bleeding. The blood is bright red, and may be lost in large quantities. Bleeding usually occurs at defæcation, although exceptionally it may occur at other times.

The Second Stage Pile.—As times goes on, from being constantly dragged upon, the pile increases in length and bulk. The tissue in the region of Hilton's line becomes raised from the subjacent muscle, the vessels become more tortuous and thickened. From repeated friction the mucous membrane becomes thickened and loses much of its bright red colour. The symptoms are less profuse and less frequent bleeding and prolapse of the pile on defæcation with spontaneous reposition at the termination of the act. The pile now becomes of the variety which has been described as mixed—that is to say, it is covered above by mucous membrane and below by skin. The skin-covered portion tends to form an external projection which is always present.

The Third Stage Pile.—The process of enlargement continues. The pile becomes much bigger and a great part of its bulk consists of fibrous tissue. The mucous

membrane becomes still more thickened and purplish in colour. Bleeding is much less frequent and may be entirely absent. The chief symptom is almost intractable prolapse. The pile has to be manually replaced after each action and even then a process of redundant skin protrudes at the margin. The main mass of the pile comes down on very slight exertion, such as coughing, bending to tie up a shoe lace, &c. Patients have frequently told me that they have been compelled to give up playing golf and billiards on this account.

Obviously, it is unlikely that the injection of an astringent solution is likely to have as much effect on the third as compared with the first stage pile. This is borne out by experience. Small first stage piles can be so effectively shrivelled by one or two injections of carbolic acid that one may confidently describe them as being really cured—that is to say, the treated pile will not again appear. This does not mean, however, that the patient will never again suffer from symptoms of piles; it is possible to develop no less than three primary and four secondary pile masses, and a patient who presents himself with, say, three small primary piles, which are successfully treated by injection, is quite likely in the future to develop a fresh crop. I think, however, it is quite possible to save these patients from operation if the piles are treated as soon as they give rise to symptoms. I have a number of cases of such patients treated as long as seven years ago who have not, so far, developed any fresh symptoms. I think the injection method by far the best way of treating the early pile. It is superior to palliative measures such as the use of ointments and regulation of the bowel in that it not merely delays the growth of the pile, but actually shrivels it up.

For the second stage pile such a successful result cannot be expected. Periods which vary in length of immunity from symptoms can, however, be obtained. Anything from two to five years' immunity can be anticipated, when the process of injection can be repeated with further good results. It is a mistake, however, to assure these patients that injection will really cure them, in the sense that for the rest of their lives they will never be troubled again with this complaint.

For the third stage pile much less relief is to be expected. The core of the pile already consists of fairly tough fibrous tissue, and any slight increase in the fibrosis will not be of much value in preventing prolapse, which is the main, if not the only, symptom which calls for relief. Further, the skin-covered portion of the pile constitutes its main bulk. This cannot be injected without causing great pain with no resulting profit. Temporary relief may be obtained by judicious injection of the upper portion of the pile. It is, however, only transient, and if a cure is wished for, operation must be advised.

Summary.

Indiscriminate operation for piles has fallen into disrepute because patients with one or two first stage piles have a few years after operation developed a fresh crop. An example of a patient for whom operation should unhesitatingly be advised is one of, say, 40 years of age, with a long history, who appears with one or more third stage piles and, on proctoscopy, shows more of them. A carefully performed operation should in such a case mean a real cure. Neither injection nor operation can be recommended unless an accurate estimate has been made of the number and stage of development of the piles. Broadly speaking, the advice which should be given to a patient may be crystallised as follows: injection should be recommended for the first stage pile always, for the second-stage pile sometimes, for the third-stage pile never. It is obvious that such a drastic summary requires qualification. For example, a patient aged 80, with troublesome third stage piles, chronic bronchitis, and a weak heart should not be advised to submit to operation when a fair measure of relief can be promised by injection.

The Technique of Injection.

The patient is best treated in the left lateral position. A good head-lamp, speculum, lubricant, ordinary record syringe, and a minim glass to contain the solution are required. The speculum I use is a modification of Allingham's rectal speculum. This is a speculum with an ebony obturator and a lateral slit, which extends the whole length of the speculum. The modification consists in occlusion of that portion of the lateral slit which lies opposite the margin of the anus. In other words, the lateral slit only extends for about three-quarters of the length of the speculum. The occluded portion prevents the loose skin at the anal margin from prolapsing into the lumen of the speculum and thus obstructing the operator's view of the upper part of the pile. I attach considerable importance to the use of this form of speculum. After it has been inserted and the obturator withdrawn, it is possible in a normal anal canal to rotate it through a complete circle with but slight discomfort to the patient, in spite of the relatively sharp margins of the lateral slit.† If any piles are present they prolapse at once through the lateral slit, and, according to the degree of prolapse, an estimate of their magnitude can be made. The speculum should be inserted in the positions in which the presence of a pile is to be anticipated—namely, in the right anterior, right posterior, and left lateral segments of the anal circumference. This involves a triple insertion of the instrument, which is undoubtedly a defect, but one which I do not see how to overcome. I formerly made use of the simple tubular speculum used by Mr. Dudley Wright and Mr. Morley. With this speculum the piles can only be seen at the end of the speculum and, when using it, I have often been in doubt as to whether piles were actually present or whether I was only observing the inevitable involution of normal mucous membrane which must occur in using this instrument. I think the use of a speculum with a lateral slit has undoubted advantages. The pile mass can be clearly demonstrated and a rough estimate formed of its size, and the point of the needle can be accurately inserted to the depth desired. In this way over-distension of the pile with the injecting material, which is probably the main cause of sloughing, subsequent infection, and secondary hæmorrhage, can be avoided.

The injection is made with an ordinary record syringe and a reasonably small hypodermic needle. The point of the needle is inserted about a quarter of an inch into the core of the pile. It is thus an interstitial injection, which is made slowly to allow the fluid gradually to work its way into the substance of the pile. I am sometimes asked if I do not insert a needle into the vein of the pile. The reply, of course, is that there is no vein in the pile, but a plexus of veins. It is a matter of chance whether the point of the needle enters one of these, and of no consequence whether it does so or not. The amount injected varies from 2 to 12 minims, according to the size of the pile. It is impossible to give any guide as to how much should be injected. It is better to err on the side of giving too little rather than too much. The thing to avoid is distending the pile to such a degree that, in the opinion of the operator, sloughing is likely to result. I usually inject two piles at one sitting. The third pile, if present, is injected a week later. The two piles originally injected receive a second injection a fortnight after the first. The process is continued at these intervals until the pile is shrivelled. For a moderate case of three early second stage piles about five or six separate sittings are necessary. Sometimes a small single first stage pile will respond to only one injection. On the other hand, during the last seven years I have injected a well-developed

† I use this procedure as a final test when examining patients I have operated on for piles to prove to my own satisfaction that I have actually removed them all.

second stage pile no less than 21 times, starting with a series of five injections at intervals of a fortnight. The owner of this pile has since been operated upon.

Lubricant.—K.Y. solution, or some form of oxycyanide paste as used for the lubrication of cystoscopes, is the best lubrifacient, since it is more easily removed from the speculum when sterilised by boiling than is vaseline or any oily substance.

Sterilisation of Instruments. — The hypodermic needles are most conveniently sterilised by keeping them in pure spirit. The speculum should be cleansed and boiled for each fresh patient, and also the record syringe. It is not necessary to sterilise the surface of the pile before inserting the needle.

Conclusions.

I would like to say that this indication of my preference for a particular injecting solution or particular technique must not be interpreted as a criticism, direct or indirect, of other methods which have proved highly satisfactory in capable hands. My preference for 20 per cent. carbolic is determined merely by its strong antiseptic powers which should as experience has shown, make its use practically fool-proof. The same considerations apply to my choice of speculum.

Far more important than the actual solution and technique employed, provided they are properly used, is the question of how far the injection method can be advocated as a cure. My own experience, for what it is worth, has led me to the conclusions which have been formulated above.

W. S. PERRIN, M.Chir. Camb., F.R.C.S. Eng.,
Assistant Surgeon, London Hospital.

Special Articles.

THE LOCAL GOVERNMENT BILL:

COÖPERATION OF PUBLIC ASSISTANCE COMMITTEES WITH THE VOLUNTARY HOSPITALS AND WITH THE LOCAL MEDICAL PROFESSION.

THE House of Lords went into Committee on Tuesday, March 5th, on the Local Government Bill, the Earl of DONOUGHMORE in the chair.

Transfer of Functions of Poor-law Authorities.

On Clause 1 Lord HENLEY moved the first of a series of amendments designed to make non-county boroughs and urban district councils with a population of 50,000 or over primary poor-law units as well as county boroughs and counties. He said he believed that this amendment would remove a number of anomalies and tend to improve the administration of the poor-law by providing a larger number of manageable units and by relieving county councils of some of their burdens.

The LORD CHANCELLOR, in resisting the amendment, said that its effect would be to increase the number of poor-law areas contemplated by the Bill from a total of 144 to 193, an addition of more than one-third. That in itself was a retrograde step, and one which was in direct contradiction of the principle of the measure. The whole basis upon which the Government's proposals were to be carried out was that of taking the country and county borough respectively as the unit for the allocation of the finance and for dealing with loss of rates and so on, and the weighting of population for poor relief among other things. Moreover, the amendment would not make for efficiency. One object of getting comparatively large areas into one poor-law area—the whole of the county except the county boroughs—was to enable county councils having a large area with which to deal to choose hospitals in which the different services which might be required for the treatment of disease to be specialised and to be concentrated. There might be in one district of a county comparatively few cases of a particular kind of illness, and yet there might be in the whole county a sufficient number to justify a hospital being devoted to its special treatment. The Minister of Health had given some instances of the very diverse kinds of case which were found being treated in one institution under the existing poor-law arrangement, and one great object which they had was to enable these wide areas to centralise in different suitable institutions the sort of treatment which was desired for particular classes of disease. If they were going to narrow and cut down the areas they would render that task much more difficult of achievement. Further, it would in some cases so emasculate the remaining part of the county, if they took the urban districts with the larger population out of it, that the area left would be quite unable to bear the burden of its poor-law.

Lord THOMSON said what could be done in the case of roads could surely be done in the case of human beings. The poor-law was not to be abolished by this Bill, only the boards of guardians, and the functions of the poor-law were being left to men who were not from their position and general attitude so likely to afford sympathetic treatment to persons who were out of work through no fault of their own. That was the argument for the amendment, and it had not been answered by the Lord Chancellor.

Earl BEAUCHAMP, in supporting the amendment, said that bodies representing areas with a population of 50,000 would be able to provide just that local knowledge of particular circumstances which was very desirable, and yet be in a position to deal with such problems as unemployment in one trade affecting the whole area.

The amendment was rejected by 78 votes to 24.

Coöperation with Voluntary Hospitals: Lord Reading's Amendment.

On Clause 4 the Marquess of READING moved an amendment to insert immediately before the proviso "In so far as such scheme relates to hospitals the council shall take reasonable steps to seek and to continue to secure full coöperation with every voluntary hospital within or serving the area of the council." He said the amendment was of very great importance to voluntary hospitals throughout the country. He moved it with the object of protecting them and of ensuring that there should be full consultation with them before any action was taken that might impair in any degree their usefulness as well as of ensuring that full effect would be given to what he understood was one of the main purposes of the Bill. The whole object of this amendment was to ensure coöperation with the voluntary hospitals and coördination of the various efforts so that there might be no overlapping of the work of, say, rate-supported hospitals, and voluntary hospitals might be consulted in order that the best might be made of existing institutions. The words he desired to insert were almost identical with those which appeared in Clause 27 of the Scottish Bill. When he put down the amendment he thought he was not going counter to the views of the Minister of Health, but rather supporting him, and he was confirmed in that view by finding an amendment on the Order Paper which proposed to insert a clause ensuring that county councils should make such arrangements as they thought desirable for securing that the functions transferred to them should be dealt with in consultation with some body in their area representing the voluntary hospitals. He would like to know whether it was proposed to introduce that provision.

The Earl of ONSLOW (Paymaster-General): It is.

The Marquess of READING said that he thought that the Government were perfectly reasonable in taking this course and that the introduction of this provision would allay the apprehensions of those who were concerned with the voluntary hospitals.

He would like to ask when this amendment had been inserted and the Bill came into effect the Ministry of Health would draw the attention of local authorities to this part of the Bill and particularly to the new provision which was being introduced. The clause as it stood was not mandatory and he was anxious that it should be emphasised that the Ministry were strongly in favour of consultation and coöperation with the voluntary hospitals and that coördination was their desire. It would be wrong to start a rate-supported hospital whose functions would overlap those of the voluntary hospital. This would injure the latter and impair the value of the medical teaching and training, the nursing and medical research which was provided by the voluntary hospital. If Lord Onslow would assure him that it would be made plain that the Government intended that there should be this coöperation and consultation he would be prepared to withdraw this amendment and others standing in his name and accept the Government's proposal.

Lord Dawson's Plea for Representation of the Local Medical Profession.

Lord DAWSON had given notice to add at the end of the clause :—

"A council in preparing a scheme under this section shall have regard to the desirability of consulting (*a*) any body existing in the area which is so constituted as to be representative of the voluntary hospitals in the area, and (*b*) any body existing in the area which is so constituted as to be representative of the duly qualified medical practitioners in the area, including those on the medical and surgical staffs of any voluntary hospitals in the area."

He said that he would speak to the amendment of Lord Reading because it was cognate to the subject of his own. For his part he did not think that the voluntary hospitals required any defence, for their work was known, and without their medical and nursing progress would not exist. If they needed support it was because of the aid that they could bring to the new hospitals which must inevitably arise. He could not contemplate that in the future there would be voluntary hospitals alone, for municipal hospitals must be established. It was true that these hospitals would arise very slowly, but that made it all the more important that in their early beginnings they should have the advantage of consultation with the great voluntary hospitals that at present existed and that they should be brought into touch with their traditions. And if that was to occur, it seems to him essential that those who did know about voluntary hospitals should coöperate with those who had had no experience up to now and who had had little or nothing to do with curative medicine. In times gone by the medical officer of health was the person, and he was now the main person responsible to the council on questions of health. As long as those councils dealt with preventive medicine that was a scheme which would work well enough. But the medical officer of health had no knowledge of curative medicine. He was not competent to deal with it. When, therefore, the councils were going to enter on the foundations of hospitals which would steadily grow year by year, it was surely reasonable to suppose that they needed to bring to the aid of the medical officers of health the assistance of those members of the medical profession who had spent their lives in dealing with the cure of disease. The whole-time medical officers in England and Wales numbered altogether 1740 men, whereas the medical men in England and Wales who were in actual practice numbered 30,000. Was it reasonable to suppose that this great and large work of hospital management into which the councils were going to enter could be undertaken by them without an organic nexus being formed between themselves and those whose lives had been spent in curative medicine? He could not see what objection could be raised to the course he suggested. It was quite easy to find a coherent body of medical men in any district as it was to find a coherent body of those representing the management of the voluntary hospitals. Experience of the poor-law was of little or no help in the administration of a curative hospital. The traditions of the poor-law were quite different. The status of the medical officers was different and they had not had the necessary experience. Indeed, experience of the poor-law might even be a disadvantage in founding a hospital if it was to approximate to the quality and work of the voluntary hospitals. It was along the line of hospitals that he saw progress in attainment of the health of the people, for in dealing with public health it would be more and more necessary to have institutional provision. Improvement in the quality of panel practice as distinct from quantity would depend very largely on the amount of institutional provision. He did not deceive himself by thinking that voluntary hospitals alone were going to be any longer adequate for the medical needs of the country. For that reason, above all others, it was essential that in their early beginnings the council hospitals should get the right tradition as well as the advantage of the long experience which the voluntary hospitals had gained. He was most anxious that there should be some machinery provided of the kind he had indicated and that it should not be left to the free will of the local authority. It should be recorded in the Bill, so that if some Minister of Health should come into office in favour of an entirely nationalised or municipalised medical service for the country it would be more difficult for him to transpose the medical policy of the country. He was not wedded to the words of his amendment, and if Lord Onslow could find some other form which would effect the object he had in view—an object which had the wide support of his own profession—he would be satisfied.

Lord JOICEY said that he was thoroughly in sympathy with the speech of Lord Dawson. At the present moment it was most important that they should not go wrong on this question. He believed that the voluntary hospitals were doing such immense good in the country that it would be a disastrous thing if their great services were not assisted generously where necessary. He certainly would be very much opposed to any hospital which could be established either by a local authority, or by a Government Department, doing anything to interfere with the splendid work which the voluntary hospitals were doing.

Need for the Goodwill of the Medical Profession as a Whole.

Lord ATKIN said he thought that the amendment which had been put down by Lord Onslow was drafted in too restricted a form. The only obligation that would be imposed on the council under that clause was that they should make arrangements for securing that the functions with respect to hospital accommodation would be discharged "after consultation with such body, if any, within the county . . . as they consider to represent the voluntary hospitals in the area." It would seen to follow that if there were no body within the county which could be considered to represent the voluntary hospitals, then no statutory obligation would be placed upon the county council at all, and he suggested that in a good many of the smaller counties it would be impossible to find such a body. No doubt there was a general hospital association, but that was not a body so far as his information went which had county committees or which could be regarded as in any way representative of the special needs of any particular county. It seemed to him that under the restricted form of the Government amendment the county council might very well proceed without consulting anybody. He preferred the words in the Scottish Bill. Moreover, the very much stronger claim which had been made by Lord Dawson was ignored by the Government amendment. It was essential, if this new scheme was to take a real hold and serve a proper part in the future welfare of the country, that it should be done with the goodwill

and coöperation of the medical profession. He supposed that the new municipal hospitals, if founded, would desire, as did the voluntary hospitals, to draw upon the goodwill and services of consultants and specialists, and surely it would be right that the scheme should be devised in the first place after consultation with the medical profession as a whole. The medical profession was organised. The British Medical Association represented for all practical purposes the whole of the profession, and had branches in every county, and therefore there should be no difficulty in regard to consultation.

Viscount KNUTSFORD said that as one who had had some experience of voluntary hospitals, he wished to say that they were extremely anxious to coöperate with the proposals in this Bill. They had no fear of competition; what they desired was that when any new hospital was started it should not overlap and do the same work as the voluntary hospitals. They expected and hoped that the new hospitals would strengthen their weakness and they were anxious to help them to do their work well.

Lord BLEDISLOE appealed to the Government to consider the smaller cottage hospitals and institutions of that type which were doing invaluable work in many parts of the country, sometimes under considerable financial stress, and were not merely serving local requirements but also assisting the counties in their administrative work. He could not help feeling that if consultation was confined to what was called a "body" in the Government amendment, these smaller hospitals would not receive representation.

Lord JESSEL said that the Government amendment seemed very nebulous, and he did not understand in the case of London what would be the proper authority. He should also like to know whether the Government were going to adopt the view so eloquently put forward by Lord Dawson in regard to the representation of the medical practitioners in the country. He hoped that the Government would consider the very strong feeling that there was on both sides of the House on this matter.

Lord GORELL also urged that attention should be paid to the case of the smaller cottage hospitals and that the Government should do something to meet Lord Dawson's point in regard to the medical profession.

The Marquess of READING said that he supported the view of Lord Dawson. The more he looked at the words of the Government amendment the more unhappy he was in regard to them. He suggested that it should not be left to the local auhority to determine the body which should be consulted as representing the voluntary hospitals in the area.

The Government's Reply.

The Earl of ONSLOW said that it was the desire of the Government to encourage as much as possible coöperation between the local authorities and the hospitals which had produced such good results in the past, and from which so much could be expected in the future. The object with which the Government and the Minister of Health was mainly concerned was to make the best use of existing institutions. It was not because of want of sympathy with those objects that the Government had found some difficulty in framing a clause to meet the wishes of noble lords. It was on the question of making statutory provision that the difficulty cropped up. It had been sought in certain quarters to make use of the analogy of Clause 7 (3), which said that county councils should consider the appointment of members of existing poor-law authorities on guardians' committees. If the hospitals had been organised in the same way as the poor-law authorities were to-day, and were statutory bodies defined in law, perhaps that analogy might have been of assistance. But that was not the case. They all knew what was meant by a voluntary hospital, but there was no precise definition of such an institution. When the Voluntary Hospitals Commission was instituted, the first thing they had to do was to devise a definition of voluntary hospitals, and a very difficult task it was. It was rendered more easy because it was done for a special purpose—namely, the distribution of a Government fund to certain institutions which were badly in need of money. The definition worked fairly well, but he did not think that it could be used at the present moment because it did not include such institutions as mental hospitals and other borderline institutions. It seemed, therefore, that the only way of meeting the wishes of noble lords was to draft the clause in as wide terms as possible, making it flexible and adaptable to every area. Areas differed very largely in administration and amount and in regard to their hospital provision. So that the Government proposed in their amendment that county and county borough councils themselves should be the judges of the bodies which might be representative of the voluntary hospitals in their areas for the purposes of consultation. The Minister of Health had authorised him to say that he would use such means as he properly could to bring by circular or otherwise to the notice of the local authorities the provisions of the new clause, and point out to them the desirability of the fullest coöperation with the voluntary hospitals. Under the provisions of the Government's new clause which he would move later, it would be open to councils of counties and county boroughs to enter into consultation with either the local voluntary hospital committees where they were functioning or where they might be resuscitated for the purpose, or with the descendants of those committees, or to utilise the committees of the British Hospitals Association as they existed at the present time, or as he believed they were shortly to be altered. As to the question of the representation of the smaller cottage hospitals, the voluntary hospitals committees, where they functioned, consisted of representatives of the local authorities both county and county borough in the area, of the medical profession, both general practitioners and consultants, of the voluntary hospitals, both of the larger type and of the cottage hospitals. Supposing use was made of the British Hospitals Association committees, any hospital had only to join the Association, a branch of which existed in each area, and its views would be available for the local authorities through that particular channel.

A New Clause at the Report Stage.

With regard to the very important point raised by Lord Dawson, he understood that the noble lord accepted the Government amendment as meeting his views as regarded the first part of his own amendment, but that he had other suggestions to make to the House with regard to the second part. He (Lord Onslow) found it difficult to accept the amendment which Lord Dawson had put down, but he understood that the noble lord did not insist upon the exact words and was ready to accept any form which the Government might put forward which would give effect to his ideas. While unable to propose anything at the moment, he hoped on the Report stage to be able to add to the clause which he had put down words which would provide that some of those who were to be consulted and who should be referred to by the county councils or county borough councils should be representatives of the medical profession in the district. He hoped that the two together would make a clause which would be acceptable to those of their lordships who were so deeply interested and so cognisant of all matters connected with hospitals and their work, and would secure close coöperation and consultation with voluntary hospitals in different districts.

Earl RUSSELL said he thought it was clear to Lord Onslow that it was the general sense of the House that this matter must be settled in a way that would be regarded as satisfactory by those who knew most about it. He had no doubt that the noble earl would take that warning.

The Earl of ONSLOW: We are all equally anxious to have the matter settled in the manner that the noble earl has indicated.

Lord HANWORTH said that the Government's new clause was drawn so loosely that it was quite ineffective. Something of this sort was really necessary :—

"The Council of every county and county borough shall"—

and then they ought to introduce the latter portion of the clause—

"after consultation with such body within the county or county borough as represents the voluntary hospitals in the area, and anybody constituted to be representative of the duly qualified medical practitioners in the area, make such arrangements as they think desirable."

Without some condition of that kind put in at an early stage of the clause it was impossible to carry out the real intention of the House.

The Marquess of READING, in withdrawing his amendment, said he hoped that Lord Onslow would consider what language would adequately meet what the House desired.

Lord DAWSON intimated that he would not move his amendment at that stage. He said that he took that course in the hope that they would get something more out of the Government than good intentions. He did not want them, on the one hand, to dissemble to the medical profession, and on the other to kick them downstairs. The more he looked at the amendment suggested by the Government the more it seemed to fall under that head. It really gave them very little. He hoped that in recasting the clause the Government would fall in with the excellent suggestion of Lord Hanworth and give them something clear and definite which would bring in contact those who were going to administer with those who really knew something about it.

Alternative Powers of Giving Assistance.

On Clause 5 Earl RUSSELL moved an amendment to include any other local or general Act among the Acts mentioned in the first section of the clause.

The LORD CHANCELLOR, in resisting the amendment, said that so far as the Government knew there was only one other Act, except those set out in the clause —namely, the Lunacy Act—which had been deliberately excluded in view of the rather comprehensive legislation relating to the lunacy law which the Government hoped to introduce later dealing with the Royal Commission's Report.

The amendment was negatived without a division.

The New Clause.

On Wednesday, March 6th, the Earl of ONSLOW moved after Clause 12 to insert the following new clause :—

Consultation by councils of counties and county boroughs with bodies representing voluntary hospitals.—"... The council of every county and county borough shall make such arrangements as they think desirable for securing that the functions transferred to them under this part of this Act with respect to the provision of hospital accommodation will be discharged after consultation with such body, if any, within the county or county borough as they consider to represent the voluntary hospitals in the area."

He said that he moved the clause in accordance with the undertaking which he gave to Lord Reading on the previous night. It was subject to the promise given to Lord Dawson that on the Report stage he would add words to provide for consultation not only with the representatives of the voluntary hospitals in the district—that was the county or county borough—but also with the medical and surgical staffs of the voluntary hospitals. He would like this amendment to have the fullest consideration and therefore he begged their lordships to allow him to postpone any further observations until the Report stage.

The Marquess of READING said that he was quite satisfied with the promise of Lord Onslow that he would undertake to consider the language of the clause before the Report stage ; it was a little difficult to accept it as it stood.

The Earl of ONSLOW assured the noble marquess that any observations that had fallen from the noble lords during the previous day's debate would receive the most careful attention.

Lord COZENS-HARDY said that the words "within the county or county borough," and "in the area," would hardly carry out the intentions of the clause. Hospitals, particularly those to which medical schools were attached, had fairly definite spheres of influence, but they very seldon marched with the boundaries of the county or county borough. That point, he thought, should be taken into consideration in reconsidering the words.

Its Wording to be Reconsidered.

Lord DAWSON had given notice to move as an amendment to the proposed clause to add the words : "and with any body existing in the area which is so constituted as to be representative of the duly qualified medical practitioners and of the medical and surgical staffs of the voluntary hospitals in the area." He said that as Lord Onslow had stated that he had not had time to consider the language of this clause, he (Lord Dawson) would suggest to their lordships that it was unwise to commit themselves to a wording which admittedly did not meet the wishes of those who desired the voluntary hospitals to be taken into account. Would it not be better to reconsider the whole matter? If Lord Reading thought otherwise he was prepared to defer to his greater experience.

The Marquess of READING said he would prefer to have the clause inserted at that stage. He was quite content with the statement of Lord Onslow that he would consider the language of the clause before the Report stage when the House would have an opportunity further to consider the matter.

Lord DAWSON said he fully accepted the judgment of Lord Reading in the matter. Lord Onslow, on the previous day, told their lordships that he would try to find words which would meet the words of his (Lord Dawson's) amendment. He would remind the noble earl, since he had said that day that he would try to meet him on the question of the representation of the medical and surgical staffs of the hospitals that that was not all that was wanted. He wanted a body "representative of the duly qualified medical practitioners and of the medical and surgical staffs of the voluntary hospitals." He would add that the people who were concerned with hospitals in that connexion and had experience of them numbered something like 30,000, whereas those who were concerned with whole-time administrative duties, the medical officers of health and other whole-time officials, numbered only about 17,000.

Lord ONSLOW's new clause was agreed to.

Lord DAWSON said he would not move the amendment of which he had given notice.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Health Propaganda.

As it leaves the Commons the Scottish Local Government Bill contains an important new clause enabling county councils and town councils to contribute from the rates to a central body or committee for the purpose of health propaganda. This has arisen out of the arrangement between the Scottish Board of Health and the Scottish Committee of the National Council of Social Hygiene. To this Committee the Board, as the Ministry in England, gave a direct grant for carrying out approved programmes of propaganda. Now the whole burden will be placed on the local authorities, who receive definite powers of contribution. The greater local authorities in Scotland have always been sympathetic to propaganda in their own district against venereal disease, and the V.D Regulations conferred on them full powers to spend money on education and demonstrations of every practicable kind. As they have already found the work of the Scottish Committee highly

satisfactory and as they have never hesitated to send delegates to the conferences, they will probably continue to support the Committee's work on the new footing. The position of venereal disease is peculiar in that a local authority normally has a large proportion of cases coming from outside its own area. There is therefore room for a central propagandist body, which is not in any sense an alternative to the work of the local authority itself. It is also important to add that the new clause applies to all forms of health propaganda. This is new and important. The placing of responsibility for health propaganda on the local authorities, subject to central direction, is really more in the tradition of Scottish administration than the method of direct central grants to independent bodies. The concern about venereal diseases in the various areas is not as acute as it was ten years ago; but curative work is maintained at a very high standard and the loss of popular interest may be balanced by the gain in the popularity of the clinics. One thing is certain—namely, that the local authorities have nowhere used to the full their existing powers of educational propaganda and teaching.

Presentation to Sir Leslie Mackenzie.

On Feb. 23rd Sir Leslie and Lady Mackenzie were entertained to luncheon by the Scottish Branch of the Society of Medical Officers of Health and the Scottish Society of School Medical Officers. Dr. Thomas Adam, President of the former Society, was in the chair, and Sir Leslie received his portrait in oils at the hands of Dr. A. K. Chalmers. In making the presentation Dr. Chalmers spoke of the changes in the work of the Scottish Board of Health during the period in which Sir Leslie was its medical member. With all the principal movements in the public health services in the last 25 years he had been intimately and honourably associated. His inquiries with Prof. Matthew Hay into the physical training of school-children had led to the physical education of the school-child, and here Dr. Chalmers recalled the part Lady Mackenzie had played in promoting the further care of the "toddler." Dr. John Macintyre, President of the Society of School Medical Officers, said that the birth of the school medical service, with which Sir Leslie had been so closely associated, was probably the most outstanding event in State medicine in the last half century, and for that alone their guest would hold a foremost place in the annals of public health administration.

In returning thanks Sir Leslie Mackenzie said that no meeting could give him more profound satisfaction than the present gathering, which represented every phase and stage of his work in the public health and school administration of Scotland. Reviewing some aspects of this work he said that for three years after presenting his report, with Prof. Hay, to the Commission on Physical Training, he had spent a great deal of his time in lecturing on the medical inspection of school-children, to which the profession was at first unfavourable. The younger generation, however, had seen that they had at last succeeded in bringing clinical medicine on to the preventive plane; and inspection gave rise to a demand for treatment. As he had almost all his life from time to time been a teacher and had taught "everything from infants in the elementary schools up to candidates for the Cambridge moral sciences tripos and the London D.Sc., not to speak of arts and medical pupils and the general public," he looked on medical examination and treatment of school-children as among the most important things he had ever had a hand in. Twenty-five years ago everybody was speaking of infant mortality and to-day they spoke of child health or child welfare, and here also as in housing, Sir Leslie Mackenzie was able to claim that he had played a certain part. He concluded by speaking in warm terms of the value of the work done by the civil service.

Lady Mackenzie also expressed her thanks, and Dr. A. S. M. Macgregor proposed a vote of thanks to the painter of the portrait, Mr. Henry Kerr, R.S.A.

The Usher Institute.

Prof. P. S. Lelean's recent lecture to a branch of the Edinburgh Women Citizens' Association on the teaching of sex hygiene was a lucid and effective exposition of the problem and of the necessity for educational action. He has previously spoken on the same subject in Glasgow, under the auspices of the Corporation and the Borough Insurance Committee.

Not long ago Prof. Lelean arranged at the Usher Institute a demonstration of child welfare work for the Scottish medical officers of health, and a special demonstration of teeth and eyes for the school medical officers. For the eye demonstration Dr. George Mackay lent his beautiful and extended series of eye pictures, which are among the best ever made. For the dental demonstration the Dental Board of the United Kingdom lent their fine exhibit of teeth models, which was originally prepared by the Edinburgh Dental Hospital, under Dr. Guy and is available for "Health Weeks" and the like. It is obvious that the Usher Institute is rapidly becoming an active educative centre for medical officers, health visitors, teachers, and others responsible for health demonstrations or propaganda. The museum has now been remodelled to include a permanent exhibition of child welfare and related work.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Infectious Diseases Regulations.

THE Minister for Local Government and Public Health of the Irish Free State has issued Public Health (Infectious Diseases) Regulations to supersede the Regulations issued in 1919. They are to come into operation on April 1st. The following diseases are rendered compulsorily notifiable: acute primary pneumonia, acute influenzal pneumonia, malaria, and dysentery. A case of malaria occurring in an institution and induced for therapeutic purposes is not notifiable, but if such patient leaves the institution while still, in the opinion of the practitioner, liable to recurrences of the disease, the medical officer of health of the district in which the patient is going to reside is to be notified. The fees for notification are 2*s.* 6*d.* for cases occurring in private practice and 1*s.* for cases occurring in the practice of a medical man as medical officer of any public body or any institution. Regulations are made defining the duty of a medical officer of health in regard to investigating the source of infection in cases reported to him, and preventing the spread of infection. Sanitary authorities are empowered to make arrangements for testing susceptibility to diphtheria and administering protective agents. Detailed instructions are given as to the procedure to be adopted by the medical officer of health in dealing with malaria; typhus and relapsing fever; and enteric fever, diphtheria, and dysentery.

The issue of the Regulations is a gratifying evidence of the increased attention given to matters of health by Government authorities in recent years.

Goldsmith and Medicine.

Dr. T. P. C. Kirkpatrick, honorary lecturer in the history of medicine in the University of Dublin, gave a lecture in the School of Physic recently on the relations of Goldsmith and the Medical Profession. He gave a sketch of Goldsmith's life as a student in Trinity College, where he took the degree of B.A. in 1750. His course seems to have been an average one. He had been thanked by the board for his diligence, and he had also been reprimanded. His relations with his tutor were not happy, and it was likely that the menial duties attached to his position as a sizar were galling to one of his high spirit. There was no reason to believe that while at Dublin he contemplated studying medicine, or

that he had any connexion with the School of Physic. In 1752 he began the study of medicine at Edinburgh, and appears to have been a fairly diligent worker. His comments on the teachers of the time are given in a letter to his brother. He left Edinburgh after a couple of years without a degree, but this was the common practice of the time. Whether he ever studied medicine at Padua or elsewhere on the Continent is unknown. At any rate some years later he is found practising medicine at Southwark, but an offer of a surgeoncy in the service of the East India Company fell through on the ground that he had no professional qualification. In 1763 and thereafter he styled himself "M.B.," and though no documentary record has been found to show the source of this degree, Dr. Kirkpatrick thinks it likely that Goldsmith had been granted the degree by the University of Dublin. It was quite in accordance with the practice of the University at the time to grant such a degree in absentia on evidence of study such as Goldsmith was in a position to show, and the records are very imperfect. There is a newspaper paragraph to the effect that he had received the degree of M.B. at Oxford ad eundem, a fact which would be explained if he already had the degree from Dublin. The charge that Goldsmith had misled the authorities of Oxford as to his standing at Dublin is unlikely to be true. Dr. Kirkpatrick closed his lecture with an account of Goldsmith's final illness.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Danger (to the Surgeon) of Cosmetic Operations.

THE case which has recently so disturbed the medical profession and intrigued the public is briefly as follows. A certain Madame Le Guen, formerly employed in an important position by a dressmaking establishment, was meditating matrimony, and in this connexion was greatly distressed over the lack of symmetry of her legs. She consulted an eminent Parisian surgeon, Dr. Dujarrier, and explained to him how suicidal she felt over the situation. Moved by her obvious distress, he consented to perform an operation which would reduce the circumference of her right leg and render her more symmetrical. Her skin proved insufficiently elastic, and the circulation in the limb inadequate. Gangrene supervened, and the leg had to be amputated. On Monday, Feb. 25th, judgment was given in favour of the plaintive patient, who was awarded 200,000 francs damages. In the course of the proceedings a tribute was paid to Dr. Dujarrier's high character by the court, but in the judgment it was pointed out that even if he had committed no mistake in the technique of his operation, he could not escape responsibility for the unfortunate results. In this matter the defence was on the horns of a dilemma; to confess to faulty technique would be to weaken the case; but, on the other hand, if the technique of the operation had been perfect, it followed that Dr. Dujarrier had recommended an operation which, even if conducted with the best of skill, might end in tragedy. As for her suicidal state of mind being a justification for the operation, the court found that this complication suggested the need of psychiatric rather than surgical aid. The lay press is disquieted as well as keenly interested in this judgment which, if it is not reversed by an appeal which is said to be impending, will hamper, if it does not completely paralyse, the cosmetic surgeon. Already heavy fines have been imposed on several skilled radiologists who, in attempting to remove superfluous hairs, have burned their patients' skins. Even the expedient of obtaining from the patient a promise in writing that she will not turn on the doctor and rend him if he is unsuccessful is likely to fail him. For, according to the judgment in the present case, a document containing such a safeguard would be considered invalid on the assumption that the signatory was, at the moment of signing, so set on his or her object that he or she was hypnotised by it, and could, therefore, not be held responsible. Considering how much French surgeons have contributed to the art of plastic and cosmetic surgery in connexion with mutilated victims of the war, it seems hard that this branch of surgery should have become so perilous for the surgeon himself.

Fatal Accidents in the Streets of Paris.

The Parisian Prefecture of Police has just published statistics which show that in 1928 there were 278 fatal street accidents in Paris itself, and 241 in its suburbs. Pedestrians accounted for 68 per cent., cyclists for 14 per cent. and drivers of vehicles for 18 per cent. In 43 per cent. of all the cases the victims were themselves responsible for the accidents, and in the case of pedestrians as great a proportion as 58 per cent. were to blame. A classification of the accidents according to the vehicles concerned showed the following figures: taxicabs, 68, in 32 of which the driver was to blame; private cars, 185, in 105 of which the driver was to blame; heavy vehicles, 151, in 77 of which the driver was to blame; motor-cycles, 23, in 18 of which the rider was to blame; bicycles, 13, in 7 of which the rider was to blame; horse-drawn vehicles, 15, in 8 of which the driver was to blame; tramways, 50, in 9 of which the driver was to blame; motor omnibuses, 13, in all of which death was due to the imprudence or neglect of the regulations on the part of the victim. The most dangerous hours of the day were between 4 and 6 P.M. (80 deaths) and between 6 and 8 P.M. (112 deaths).

MEDICINE AND THE LAW.

Lunacy Certification.

DURING debates on the Local Government Bill it has been stated that the reform of the Lunacy Law is recognised as urgent but cannot be fitted into the Bill and must await the attention of some future Parliament. Some comments by the Chief Constable of Chester during criminal proceedings on March 6th may help to persuade the public that reform is urgent. Two persons were before the court. One was a boy of 18, charged with attempted suicide by cutting his throat in a crowded thoroughfare in the town. The other was a sheep-dealer from North Wales, aged 37, charged with cruelty to sheep by leaving them without food in a field during the recent frosts when five of the animals died of starvation. Both the accused had been under medical observation but, according to the Chief Constable, the doctors, while declaring them to be insane, refused to certify them under the Lunacy Act in view of litigation in the High Court where heavy damages had been awarded against a medical practitioner for alleged negligence in certification. The boy was placed on probation for two years; the sheep-dealer was remanded to prison for further medical observation. The Chief Constable is evidently pessimistic in the present state of the law. Recently, he said, a person was certified at Chester by the prison doctor, but, on the case being sent to the poor-law authority, their medical officer declined to certify.

No reform of the Lunacy Act will eliminate honest differences of opinion among practitioners, but the grant of reasonable protection to the certifying doctor will at least overcome his present hesitation to take a personal part in a procedure which exposes him to heavy financial loss. Meanwhile one may take note of the phenomen on that those concerned in administering the criminal law, who often accuse the medical profession of discovering proof of lunacy too readily, can also complain that the profession is too slow in detecting it.

Injections by Probationary Nurses.

At an inquest at Deptford on March 6th on the death of a woman in the Bermondsey and Rotherhithe Hospital, the coroner (Dr. W. H. Whitehouse) found that death was due to septicæmia following the injection of drugs into the arm as a treatment for heart disease given by probationary nurses at the

hospital. From the evidence of Dr. R. C. Harkness, medical superintendent of the hospital, it appeared that the injections included digitaline and anti-streptococcus serum and that they had been administered by five persons. Four of these were probationary nurses, one in her second year, two others in their fourth year, and the fourth about to take her final examination. Dr. Harkness said he regarded them all as trustworthy. Asked by the coroner why the injections were not given by medical men, he replied that it would not always be practicable as they have to be given at all sorts of hours. Asked why they should not be given by the sister of the ward or staff nurses, he answered that the probationers were under training and must have a certain experience to learn their duties. Probationers, he added, have to give injections in the course of their training and this is usually done under the supervision of the night sister. The coroner observed that it did not seem right that alkaloids like digitaline should be given by probationers in the middle of the night; he thought that a fully trained nurse should be present to supervise such injections. A verdict of "accidental death" was recorded.

MEDICAL SOCIETY OF LONDON.

ANNIVERSARY DINNER.

THE 156th Anniversary Dinner of the Medical Society of London was held in the Empire Rooms of the Trocadero Restaurant on Friday, March 8th, Dr. J. W. CARR, the President, presiding.

The toast of the evening, Prosperity to the Medical Society of London, was proposed by Mr. Justice MCCARDIE, who pointed out that, such was the antiquity of the Society, the earlier dinners would have taken place when Burke was still speaking in Parliament, Johnson was walking down Fleet-street, and Boswell was taking notes. Mr. Justice McCardie recognised as two outstanding qualities in the medical profession their sense of enjoyment of life and their accuracy in their work—to the doctor, he thought Babbage's correction of Tennyson would appeal, when the eminent calculator pointed out to the poet that his well-known lines should have run: "Every moment dies a man; every moment one and one-sixteenth of a man is born." Judges and doctors, he said, alike were occupied in searching for the truth, and in his own case he sometimes found it hard to discover; as, for example, when, in a motor-car accident the usual dilemma was reached, and reached through evidence, that each car had throughout been on its own side of the road, that each car had been under perfect control, and that each car had been stationary for an appreciable time before the collision occurred. Sir Henry concluded by pointing out the gain to society of professional associations, and the certainty that the sense of corporate responsibility and of trusteeship, engendered by them, would develop. In this development of trusteeship the value of tradition would have full play, and, while society as a whole might be on the threshold of fundamental changes, medicine would be safe because of the general recognition of the beneficence of medical aims.

The PRESIDENT, in reply, compared the position of the Medical Society of London, standing without the Royal Society of Medicine, to the position of England, a homogeneous country, and of America, an amalgamation of well-nigh 50 States. He gave his reasons for thinking that the Medical Society had done well in preserving its individuality, and called attention to three particular features by which it was distinguished. First, he said, it possessed a library which housed a unique collection of manuscripts, and of these a proper display had now been made possible by the work of Dr. A. F. Voelcker, the librarian, and Mr. Haines Carter, the secretary of the Society. Secondly, the Society conducted its business with no sectional divisions—its scientific voice was one and undivided. And with regard to the tendency to specialism, indicated by the treatment of disease under sections, Dr. Carr wondered who, when the whole of pathology had been regionally allotted to various specialists, was going to give a general medical opinion, and who was going to educate and examine students on general lines. Thirdly, he said he would refer to what was supposed to be a mediæval characteristic of the Society—namely, that membership was exclusively confined to males—to him a singular situation seeing that, through his official position, he had been instrumental probably in passing into the medical profession so many of the women who might have become members. He admitted that a plebiscite of the Society had recommended their admission, but the inactivity of the council in the matter had met with no protest. Dr. Carr closed his speech by referring to the financial condition of the Society, which, he said, was a very good one, for they had bought their freehold and had every reason to believe that as long as London was an Imperial capital their property would not depreciate. But he suggested that there was room for donations and that immortality could be earned by wiping out the Society's debts.

Mr. WARREN LOW proposed the Health of the Guests, and commenced by stating that the Society had inherited the tradition of hospitality from its founder. Among those whom they welcomed that night, he said, were the Master of the Apothecaries Society, the Presidents of the British Medical Association, the Royal Society of Medicine, the Chelsea Clinical Society, and the Hunterian Society, and the Editors of *The Lancet* and the *British Medical Journal*. Journalism, he said, had now become one of the great professions, and, while the Church made money out of the sins of society, medicine out of its diseases, law out of its misfortunes, journalism, it seemed, throve on its indiscretions. He regretted, however, the place that popular medicine appeared to be trying to play in lay papers, where the life work of a respectable organ like the spleen was trying to replace the details of a divorce case, to which publicity was now refused. He coupled with the toast the names of Lord RIDDELL and Sir EWEN MACLEAN, both of whom replied briefly.

Public Health Services.

INFLUENZA.

THE epidemic is now definitely declining in Manchester and other Lancashire towns, as well as in Liverpool and Cheshire; it is on the wane in most districts of London as well as at Portsmouth. But influenza is still widely prevalent in the North of England, the Yorkshire towns, and the Midlands generally, as well as in some parts of Wales. The epidemic is stated to be at its height at Newport, Isle of Wight; Shropshire is the only locality where it is reported to be on the increase. Nearly all localities report a mild type of the disease, but an increase in pneumonia is noted in some of the Lancashire and Yorkshire towns. In the week ended March 9th the mortality-rate from all causes rose to 41·8 per 1000 in Sheffield and 46·6 in Birmingham, the latter figure being the highest ever recorded in the city.

Abroad a marked increase of the general death-rate and of deaths attributed to influenza occurred in the Rhine area. Towns which normally have a very low mortality are now reporting death-rates as high as 32 in Cologne and 36 in Elberfeld and Barmen. The fall in the death-rates following the decline of the epidemic in Northern Germany, as well as in the Scandinavian countries, has been delayed by the extreme cold which persisted in February. The epidemic seems to be gaining new territory in some of the Baltic districts, the death-rate for Königsberg having gone up to 28. The epidemic, which is mild in character, is extending eastwards in Czecho-Slovakia and Hungary, though now decreasing

in the western parts of these countries. Wurtemberg, Southern Bavaria, and Switzerland are so far little affected. From Denmark comes the news that influenza, although decreasing in the towns, is still increasing in remote rural districts. In Spain the death-rate is still high in certain towns, but the epidemic is now generally on the wane. In Iceland the epidemic reached its maximum at Reykjavik during the week ending Feb. 16th and then declined rapidly. In Madagascar influenza is epidemic at Tamatave and in various inland provinces, but is causing only a few deaths.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED MARCH 2ND, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 288; scarlet fever, 1958; diphtheria, 1114; enteric fever, 26; pneumonia, 5874 (last week, 4451); puerperal fever, 51; puerperal pyrexia, 146; cerebro-spinal fever, 13; acute poliomyelitis, 8; acute polio-encephalitis, 3; encephalitis lethargica, 23; dysentery, 5; ophthalmia neonatorum, 83. No case of cholera, plague, or typhus fever was notified during the week.

Notifications of pneumonia have again risen considerably, the figures for the last six weeks being 1864, 2422, 3511, 3898, 3658, and 4451. Counties reporting the largest number of cases of pneumonia are as follows: London, 460 (last week 554); Chester, 148 (155); Derby, 106 (53); Durham, 345 (244); Essex, 153 (128); Kent, 130 (92); Lancaster, 862 (783); Leicester, 90 (52); Middlesex, 180 (189); Northumberland, 211 (167); Stafford, 462 (209); Surrey, 14 7(78); Warwick, 552 (313); Yorks, West Riding, 921 (597)—the North and the Midlands contributing most of the increase.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on March 5th–6th was as follows: Small-pox, 41 under treatment, 2 under observation; scarlet fever, 1716; diphtheria, 1912; enteric fever, 10; measles, 65; whooping-cough, 1057; puerperal fever, 15 (plus 4 babies); encephalitis lethargica, 79; poliomyelitis, 8; "other diseases," 63. At St. Margaret's Hospital there were 7 babies (plus 5 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns including London there was no death from small-pox, 3 (0) from enteric fever, 94 (4) from measles, 17 (4) from scarlet fever, 275 (86) from whooping-cough, 48 (4) from diphtheria, 60 (14) from diarrhœa and enteritis under two years, and 2183 (424) from influenza. The figures in parentheses are those for London itself.

The number of deaths from influenza during the previous eight weeks was 99, 122, 179, 321, 652, 987, 1243, and 1764 respectively, the figures for London during the same weeks being 18, 34, 39, 77, 198, 331, 393, and 473. In the week under review deaths were attributable to influenza in Birmingham, 229; Leeds, 139; Sheffield, 74; Stoke-on-Trent, 73; Manchester, 71; Oldham, 57; Leicester, 56; Hull, 45; Sunderland, 37; Bradford, 33; Middlesbrough, 31; Bolton and Newcastle-on-Tyne, each 30. (Glasgow reported only 12, Edinburgh 21, Dublin 19, and Belfast 6.) The figures for the week ended March 2nd to complete the Registrar-General's comparative table of influenza death-rates (printed last week but one) are as follows: Aggregate, 5·78; North, 6·26; Midland, 7·57; South, 4·52; Wales, 1·87; Greater London, 5·04; Birmingham and Liverpool each reported 13 deaths from measles, Sunderland and Cardiff each 7. Deaths from whooping-cough are still widely distributed, the highest figures coming from Bolton and Manchester, each 13; Salford, 12; West Ham and Oldham, each 11; Leeds, 10. No great town has more than 8 deaths to report from diarrhœa.

The number of stillbirths registered during the week was 289 (corresponding to a rate of 43 per thousand births) including 45 in London.

The Registrar-General continues his instructive table showing the number of deaths, especially among old people, from influenza and from respiratory and circulatory diseases in London during the recent severe weather. The supplementary figures (namely, 424, 212; 828, 405; 634, 463) are with the exception of the last all considerably lower than in the preceding week.

Correspondence.

"Audi alteram partem."

THE INJECTION TREATMENT OF VARICOSE VEINS.

To the Editor of THE LANCET.

SIR,—In replying to Prof. Archibald Young's letter I am not a little embarrassed by the fact that my recent Hunterian lecture has yet to appear in your columns. But since your annotation on this lecture has led Prof. Young to such a denunciation of injection methods, I feel it is necessary to answer his charges. The charges levelled against injection treatment are as follows. It is too simple; it is carried out without any or sufficient justification; it is unscientific, therefore unsurgical; the risk of fatal and non-fatal complications is greater than is generally admitted; there are many failures of the method; and, finally, it is not as effective as operation in cases that really require treatment. The very diversity of these charges makes it difficult to believe that the subject has been approached in a detached or critical spirit, and certain of the charges themselves suggest that criticism has been clouded by prejudice.

The only virtue conceded to injection treatment is its simplicity, and this virtue Prof. Young at once converts into a vice in that it may tempt the inefficient to carry out the method. That this simplicity may *conceivably* lead to abuses I admitted in my lecture, but to employ such a type of argument against a new therapeutic measure is paltry. If radium treatment should eventually prove superior to operation in the treatment of carcinoma of the breast, it would be unjustifiable to argue that it should be denied because it is technically simpler than the standard operative procedure. The temptations which lie in wait for the inefficient are not confined to injection treatment.

Secondly, to make the charge that a therapeutic measure *may* be used without any, or sufficient, justification, is to attempt by totally irrelevant means to obscure the issue as to the exact value of that measure. Such charges might be made against many established therapeutic methods, but they do not in themselves detract from the true value of those methods, but are rather reflections on the weakness and cupidity of certain individuals. Prof. Young suggests that treatment given with insufficient justification has gone to swell the statistics, but in a disorder which is fundamentally progressive patients are, as a rule, unwilling to undergo, or surgeons to advocate, operation at a comparatively early stage. At a late stage few surgeons will advise operative treatment. In my own series of over 200 cases more than 50 per cent. were considered inoperable either on account of age, general condition, or owing to the presence of ulcers or dermatitis; 40 per cent. were considered suitable cases for operation; and only 10 per cent. could be classed as early ones—that is, cases in which the surgeon would not advocate and the patient would not willingly accede to operation. Surely from the point of view of rational therapy these early cases are the ideal ones to get before symptoms are severe and before complications have arisen. The preponderance of the other groups is a witness to the failure of operative treatment to deal at all adequately with the situation.

Prof. Young's third contention is that injection treatment is unscientific and therefore unsurgical. His letter does not contain one single argument in support of this statement. If, as I suppose, it is based on the assumption that the production of intravenous thrombosis is necessarily unsound, it is certainly fallacious. What happens in the ordinary ligature and excision operation on varicose veins? The answer is that thrombosis occurs in the blind

ligatured stump of the vein; this thrombosis is mainly due to the stagnation of the contained blood, and for this reason is much more likely to be lightly adherent than when it occurs secondarily to endothelial damage. It is from this stagnation thrombus that pulmonary emboli occur after operative measures.

Fourthly, statistics show that as far as the risk to the patient is concerned it is certain that the chance of embolus occurring after injection treatment is many times more remote than in cases which have undergone the various forms of operation. In any operation involving the ligature of a varicose vein the danger of embolus is never entirely absent, and the incidence is higher than the general incidence of post-operative emboli. If the theoretical danger of pulmonary emboli is to deter us from the treatment of varicose veins, the danger must be given much greater consideration in discussing operative than in discussing injection treatment.

Fifthly, the failures of injection treatment are mustered against the method. The method is new, its employment has been largely experimental, and its technique often halting, and I do not doubt that there have been failures. In my own experience, and I know this is confirmed by that of many others, I have yet to see a case in which I failed to achieve thrombosis and sclerosis of the veins with corresponding relief of symptoms. Failure in this respect is certainly due to faulty technique. Similarly, with proper technique, the local lesions which are sometimes seen, can be reduced to negligible proportions. Applying similar arguments to operative methods, it will be admitted that failure is not unheard of and sepsis not unknown.

Sixthly, Prof. Young calls in question the efficiency of the method in cases which he considers really require treatment. Clinical experience of injection treatment shows here that the functional results obtained are as good as those obtained from ideal operations, and cosmetically much better, to say nothing of the fact that the treatment has been ambulatory.

I will conclude by quoting the sentences from the annotation to which Prof. Young has taken exception.

> This treatment is so simple, so effective, that it has ousted almost completely the treatment by operation . . . on the whole, it can be said that the injection methods now generally adopted are suitable for routine use. The risk is less than operation and the results are better.

The facts as here stated are strictly accurate and based on experience, and since surgery is a practical art, they are not likely to be gainsaid by purely theoretical considerations.

I am, Sir, yours faithfully.

Harley-street, W., March 6th. REGINALD T. PAYNE.

To the Editor of THE LANCET.

SIR,—Everyone with any extensive first-hand experience of the actual operation of the "injection" of varicose veins, and of its results, will unhesitatingly support Dr. Christopher Howard and Sir Sidney Alexander in their disposal of Prof. Archibald Young's objections to that treatment.

To the category of otherwise healthy patients suitable for the injection treatment—viz., those who unshakably (and I think very reasonably) connect their pain, fatigue, discomfort, and unsightliness with their leg varicose veins, whether these be very varicose or not; and those with varicose ulcers; and those (not few) whose varicose veins have recurred after one, or more, excision-operation; and those, often quite young men and women, rejected for some service or other on account of varicose veins, though, as often happens, these veins had so far caused no discomfort or disability; I would add, also from my own practice, one more, "not otherwise healthy"—viz., those middle-aged or even old patients whose activities are curtailed and life made uncomfortable by reason of varicose veins, but whose age and general state of health—e.g., more or less chronic bronchitis—have made, or will make, the surgeon refuse them a general anæsthetic and excision-operation. They can safely be cured of varicose veins by the injection treatment, given cautiously with fewer injections at a sitting and longer intervals between sittings. Their own opinion is that almost a new lease of life is thereby given them.

In fact, with the growing confidence of doctors and public in the treatment and its results, all but one of the above types of varicose vein patients will become rare, instead of as now, common; for the practice of early injection of varicose veins so soon as they appear will become universal. This, however, will often mean injection of quite small varicose veins in "quite young girls"—to Prof. Young's dismay.

I am, Sir, yours faithfully,

H. M. HANSCHELL.

Weymouth-street, W., March 9th, 1929.

SPINAL ANÆSTHESIA IN ABDOMINAL SURGERY.

To the Editor of THE LANCET.

SIR,—A hasty statement of mine in your issue of Feb. 16th concerning the action of gravity and "diffusion" was severely criticised by Prof. Pannett, and as I clearly recognised that the wording was both unscientific and calculated to mislead, I thought that in the circumstances the most graceful, if perhaps not the most sensible thing to do, was to publish an admission of error in your following issue. But I find that Mr. Percival Cole (same issue, p. 468) is so obviously of the same opinion as myself as to the clinical findings and makes the same mistake in the unscientific use of the word "diffusion" that I make no apology for re-entering the discussion and offering what I believe to be the correct solution of the problem.

I am still of the opinion that gravity being a constant is the least important factor in this discussion, and there is no better way of describing the probable progress of novocaine in the theca than by saying that there is a progressively slow downward "diffusion" of novocaine until it comes to a natural extinction by absorption at a certain level proportional to dosage. Referring to the glass-tube experiment, Prof. Pannett states that these results cannot be applied to the human body and gives as his reason the obstructions which the solution encounters in its downward course. He misses altogether the prime factor which differentiates this experiment from a similar one in the body—viz., the rapid absorption by the tissues of the novocaine and the resulting progressive diminution in the specific gravity of the descending fluid. Referring to the body, he states (your issue of Feb. 9th, p. 276):—

> "There is no danger at all of the solution flowing up too high and causing dangerous paralysis. There are large margins of safety in the small size and small dose of novocaine solution and in the fact that the anæsthetic is quickly diminished in strength as it trickles upwards, partly because it becomes fixed by the nerve-roots, partly because of the rapid absorption which takes place from the spinal canal."

If he will allow me I will paraphrase this statement and add considerable meaning to it:—

> When the solution is injected owing to rapid dilution and absorption of novocaine, there is a progressive diminution in the specific gravity of the descending fluid, this results in a progressive retardation of the descent and a consequent increased opportunity for novocaine to be absorbed, until the specific gravity of the advancing column so nearly approaches that of the cerebro-spinal fluid that stasis results in the complete absorption of novocaine at a constant level proportional to dosage.

It will be noted that Prof. Pannett makes use of the expression "trickles upwards." It was in response to this invitation and in opposition to this conception that I left the rigid confines of physical science and used the term "diffusion." Gravity then, although its action is obvious in the early stage as shown by its

immediate effect on the underside in the lateral position, progressively loses its hold on the descending solution and will never take us to the required level unless the dose is adequate to stay the course.

I therefore offer the following theory for criticism. The accomplishment of spinal analgesia falls into three natural divisions :—

1. Block across the *lower lumbar and sacral* nerves for short operations on the perineum, &c.

Interval—the lowest—small dose 5–10 cg.

2. Block across the *root of the cauda equina*, thence involving the roots of the first lumbar and lower thoracic nerves, for operations on the legs, testis, and lower abdomen. For both these divisions no postural arrangement of the body is necessary, the patient lying horizontal, but slight inclination of the body favours paralysis of the upper segments of the rectus muscle. For unilateral operations reinforcement can be obtained by placing the patient on the affected side and keeping him thus during the induction period.

Interval L 1, L 2, average dose 10–12 cg.

3. *Splanchnic* block—up to the fourth thoracic nerve-roots and a little beyond. This requires an inclination of the body sufficient to overcome the dorsal curve, the actual angle being unimportant provided that this condition is fulfilled, though it ought not to be excessive. The level reached is dependent upon the amount of the dose used; this amount should be proportional to the probable size and therefore absorptive power of the nerve-roots in an individual case. Every dose owing to rapid dilution, absorption, progressive diminution in specific gravity, retardation of descent, increased opportunity for absorption, ultimately attains stasis and the novocaine is completely absorbed at a level proportional to the amount of the dose.

Interval L 1, L 2. Dose, 10–12 cg. ; in some big men more. In the event of partial failure a second dose is administered, the amount of such dose to be proportional to the deficiency of the result.

No amount of inclination will bring a small dose to a high level, except in the case of a secondary dose, because previous saturation favours its progress. "Barbotage" results in distributing novocaine below the site of an intended block and should never be used. The above theory is not only in accordance with all clinical findings, but in my opinion reconciles the conflicting views recently expressed in your columns.—I am, Sir, yours faithfully.

W. HOWARD JONES, M.B., B.S. Lond.,
Surgeon Anæsthetist to Charing Cross
March 11th, 1929. Hospital.

To the Editor of THE LANCET.

SIR,—Your correspondents have raised the question of the spread of fluid in the spinal theca. The Saccharine Corporation and MM. Poulenc Frères were so obliging some years ago as to carry out at my suggestion experiments in regard to the density and diffusibility of solutions employed for spinal injection. According to the reports, which I shall be pleased to send to anyone interested, diffusion was extremely slow and may be in practice disregarded. Gravity may come into play to some extent, even if a light solution is used (the 10 per cent. stovaine in saline is often supposed to be as light as the cerebro-spinal fluid), but the fact is, that experiments tell us very little of what happens in the living subject, for various physical, anatomical, and physiological complications are added ; and one may depend upon the practical result, which is, in my experience and that of many others, that a patient may be put into the Trendelenburg position as soon as an injection of stovaine in saline has been given.

I am, Sir, yours faithfully,

London, N.W., March 8th, 1929. J. D. MORTIMER.

TONSILLECTOMY IN CHRONIC ARTHRITIS.

To the Editor of THE LANCET.

SIR,—It is rather surprising that Mr. Pavey-Smith should now state that the figures of his hospital admissions from which I drew certain conclusions, were "rhetorical," as the sentence in his original paper seems plain enough : "During the time that these 200 patients were dealt with *over* 7000 cases of many and various forms of arthritis and allied conditions passed through the hospital" (my italics). Mr. Pavey-Smith now desires to cancel the 7000 and to substitute instead accurate numbers of the various conditions with which he is dealing. This is certainly more satisfactory.

Mr. Pavey-Smith gives 2333 cases of all forms of arthritis admitted. Analysing these one finds that roughly 20 per cent. of acute and subacute rheumatism show tonsillar sepsis, but that in other forms of infective arthritis only 8 per cent. were subjected to operation, 1 per cent. being cured and 4 per cent. obtaining benefit. In one only of some hundreds of cases of osteo-arthritis did the condition of the tonsils warrant interference. With these more exact figures one still finds that in arthritis, with the exception of rheumatic fever, tonsillar infection plays but a very small part. I should like to congratulate Mr. Pavey-Smith on his conservative policy when dealing with this disease.

I am, Sir, yours faithfully,

London, W., March 5th, 1929. H. WARREN CROWE.

OPERATING FOR APPENDICITIS.

To the Editor of THE LANCET.

SIR,—In reply to Prof. Grey Turner, may I endeavour to clear up one or two apparently doubtful points ? In the first place, the cases from which these statistics were compiled were divided into cases operated upon while infection was still confined to the appendix, and "the remainder," which included local abscess, local and general peritonitis. In estimating the ultimate mortality, some slight allowance must admittedly be made for the risk of interval removal, but if sufficient time (about three months), is allowed for infection to subside, then this added risk should be almost negligible.

In my lecture, I dwelt on the possibility of refusal of the patient to undergo interval appendicectomy after expectant treatment had tided him over the crisis, but I believe it is exceptional for subsequent operation to be refused—the memory of recent illness and the fear of recurrence are too vivid. At any rate, we must assume that patients are more or less reasonable, and according to our beliefs, endeavour to pilot them through an illness with the minimum of risk, in the hope that they will continue to follow our advice, and the arguments for interval appendicectomy are certainly clear and weighty.

I heartily applaud Prof. Grey Turner's condemnation of Battle's incision. I purposely refrained from mentioning it, as the sooner it falls into oblivion the better it will be for abdominal walls. I am not conversant with Rutherford Morison's "oblique muscle-cutting incision," but, personally speaking, its strongest recommendation would be to know that Prof. Grey Turner uses it himself.

Mr. Davies-Colley raises one or two points to which I should like to refer, particularly in connexion with operation when infection is localised to the right iliac fossa. Ignoring the high mortality of interfering in localising cases between the third and fifth days (over 9 per cent.), the risk of complications and sequelæ is considerable. When infection is localised efficient protection of the infected area by packing may require very wide exposure in order to avoid breaking down adhesions to the anterior abdominal wall. Infection of this extensive wound, which commonly occurs, is prone to result in incisional hernia. As Mr. Davies-Colley suggests, anxiety to leave structures in situ may prohibit closure of the appendix stump, and as drainage is usually required, the formation of a fæcal fistula is encouraged. When once localisation has occurred, general peritonitis is only likely to follow if a subsequent abscess

ruptures into the peritoneal cavity, provided that the patient is treated on established lines. As stated in my lecture, if an abscess forms and increases in size, then drainage is indicated with a view to obviate this risk, and also to shorten convalescence.

I cannot understand Mr. Davies-Colley's query, "Why drain the pelvis for an infection limited to the iliac fossa?" The point stressed was that *if* pelvic drainage was necessary it should be obtained by a separate suprapubic incision rather than through the original gridiron incision. When infection is localised to the right iliac fossa, if an appendicectomy has been attempted, then a stab wound in the loin provides direct and dependent drainage.

Mr. Hamilton Whiteford refers to the risk of mistaken diagnosis. I agree that when doubt exists, then expectant treatment is unwise; but when infection is limited to the right iliac fossa, and the other three abdominal quadrants appear normal, then the risk of an error in diagnosis is slight, and it is particularly in these localising cases that expectant treatment is advocated. The only two errors of diagnosis which I have personally seen were a volvulus of the cæcum and a twisted ovarian cyst. Both of these cases survived, in spite of a short period of expectant treatment, and I believe that a more careful clinical examination would have resulted in a correct diagnosis.

I am, Sir, yours faithfully,
R. J. McNEILL LOVE.

Harley-street, W., March 12th, 1929.

MEDIÆVAL TOWNS AND SPAS OF GERMANY.

To the Editor of THE LANCET.

SIR,—Attention was drawn in THE LANCET by a news paragraph, which appeared in your issue of Feb. 2nd, to a projected tour at Whitsuntide to the mediæval towns and spas of Germany. This tour I was organising upon the lines of previous expeditions to Czecho-Slovakia and Yugoslavia, and was aiming at having again between 20 and 30 participants. After the appearance of the notice in THE LANCET, a number of doctors wrote to me for details but have not yet decided to go. May I point out that, if the number of acceptances by the end of March falls short of 20, the tour cannot take place, as the agency in whose hands the management lies cannot for any smaller number make the proper and economical arrangements either at hotels or in trains. Prospective travellers should send a deposit of £15 to me at the Bath Club, 34, Dover-street, London, W.1, which will be immediately returned if the numbers still fall short of twenty by March 31st.

I am, Sir, yours faithfully,
HENRY BAERLEIN.

Bath Club, London, W., March 8th, 1929.

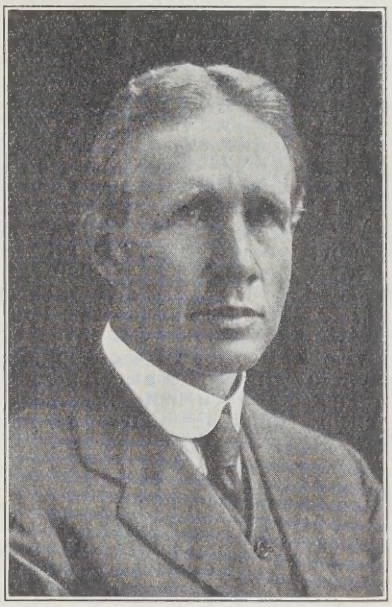
PRESENTATION TO A SURGEON.—Mr. A. W. Nuthall, who was elected surgeon to the Birmingham Children's Hospital in 1904, has just retired under the rules of the hospital after 25 years' service. In recognition of his work he has been appointed an honorary consulting surgeon and presented with a chiming grandfather clock and a drawing-room lamp; a diamond and sapphire ring has been given to Mrs. Nuthall.

IMMUNISATION AGAINST DIPHTHERA IN MANCHESTER.—At the last meeting of the Manchester City Council it was proposed that the medical representatives of the corporation should call meetings both of teachers and of parents and explain to them the advantages of immunisation. Under the scheme sanctioned in June last the education committee was empowered to undertake the prevention of diphtheria by immunisation by the Schick toxoid antitoxin method. At ten of the welfare centres the work is already in progress. Though the treatment has only been available for about six months over 1000 injections have been performed and there has not been any complaint of undesirable after-effects. In some districts the great majority of parents attending certain centres have had their children immunised, and at other centres parents are adopting the idea more slowly.

Obituary.

CLIVE RIVIERE, M.D., F.R.C.P. LOND.

Dr. Riviere, who died at his house in Queen Anne-street on March 6th, was the second son of Briton Riviere, and although he had only recently developed a latent aptitude for water-colour painting, the artistic temperament which he inherited showed itself in every aspect of his work. His bent towards clinical medicine dated from the time when he was house physician at St. Bartholomew's Hospital to Lauder Brunton, the one member of the medical staff at that time who was deeply concerned with the technique of scientific treatment, and when he was clinical assistant to Howard Marsh in the throat department. There followed the usual period of attendance in the "morning surgery" as casualty physician whose task it was to pick out from a mixed mass of suffering humanity the acute and interesting cases, and Riviere became chief assistant in the newly created children's department of the hospital; but he did not stay at Bart.'s. where the prospect of promotion on the medical side then seemed remote, and in 1902 he was appointed out-patient physician at the Victoria Park Hospital, gaining charge of beds in 1916.



DR. CLIVE RIVIERE.
Photograph by Elliott and Fry.

Throughout the 27 years of his career there, as one of his colleagues testifies, he worked hard and unselfishly for the hospital's welfare and was always ready to take on any task asked of him. He was there revealed as a clinical physician who had matured slowly. There was no sparkle or superficial brilliance about his work; he went about it with steady purpose which declined to be put out by hurry or mishap. Joining the staff about the dawn of the tuberculin era, he took an active part in the research which this new remedy entailed and collaborated in a book which still counts as the best treatise in English on tuberculin treatment. That work led him in turn into the field of early diagnosis in tuberculosis, a subject which was then much to the fore as a result of the creation of the dispensary system. Finally the introduction of treatment by artificial pneumothorax into this country by Lillingston and Vere Pearson brought out the best in him. Realising almost intuitively its possibilities Riviere soon became a pioneer and exponent of its technique. His light touch,—for percussion was to him a fine art,—his skilled fingers, and a certain quiet sureness of manipulation, combined to give him a technique which was well-nigh perfect. To these qualities time and experience added a fine clinical judgment, and wherever there was a difficult pulmonary case in hospital his advice was gladly sought by his colleagues. To the new major operations on the chest,

thoracoplasty, and the like, he brought the same mental balance. His opinion, given after much thought, was always sane and free from panic, for he was the least dramatic of men.

Riviere's published writings contain the same elements of success as did his clinical work. The first edition of each of three little volumes issued by the Oxford Medical Publications was soon exhausted and one or more reprints called for by grateful readers. In each case the love of detail and the sense of style which are both clearly visible are subordinated to the purpose of the whole, and the reader does not fail to get a perspective of the subject before him. He never wrote readily, but the third book of the series, on pneumothorax, is a bright example in modern medical writing of a whole which is greater than the sum of its parts.

In his relations with members of his own profession Riviere was happy. The courtesy and obvious sincerity of his motives kept him free from bias in hospital politics, and his sense of fitness saved him from harsh judgments. He disliked show and cheapness in anything, and his love of beauty and skill in art brought out in him a desire for high quality and personal worth. It was this personal worth which endeared him to those who worked with him. "I was greatly struck," writes a surgeon whom he attended professionally, "by the care and thoroughness with which he did his work, by his extraordinary kindness and sympathy, and by the encouragement he gave. During the past 12 years I have had occasion to consult him many times; he was always the same. It is due to his advice and treatment that I regained my health. During the last long illness of one of my family Dr. Riviere came to see him again and again, and did more than I thought possible to relieve his suffering and render his last days tolerable."

The same temperament created an atmosphere of welcome in his home and made him in request where any large scheme of public hospitality was in question. He was joint honorary secretary of the International Medical Congresses held at Lisbon in 1906 and at Budapest in 1909, but the 1913 Congress in London gave him his opportunity as hon. secretary of the Reception Committee; and none of those who attended the enormously successful function at the Natural History Museum, where Mrs. Riviere and he were responsible for the decorations and entertainment, will ever forget their debt. Riviere's charm was heightened by the fact that he held no high opinion of his own qualities or attainments; even among his intimates he only rarely emerged from a kind of constitutional shyness, and his diffidence in impressing his own opinion on others made it impossible for him to make an enemy.

He was only 56 years old when he died at the end of a week's illness from pneumonia, which came as an overwhelming infection from the start, and he leaves the stage at the moment when his powers were at their highest and best.

HENRY ROXBURGH FULLER, M.V.O., M.D. CAMB.

THE death of Dr. Roxburgh Fuller on March 7th brings to an end an extremely long medical connexion with Mayfair. His great-grandfather, John Fuller, is stated to have come up from Dorking to London in about 1767 to study at St. George's Hospital. He practised as an apothecary in Piccadilly, and among his patients was "Old Q," the eccentric William Douglas, fourth Duke of Queensbury. A very interesting account of the famous lawsuit between the executors of "Old Q" and John Fuller is told in a book entitled "Old Q and the Apothecary," by the son of Dr. Roxburgh Fuller, which was printed some years ago. The lawsuit was of the greatest importance to the medical profession, for a direct outcome of it was the passing of the Apothecaries Act of 1815, which settled the legal status of the general practitioner. The lawsuit was the result of Old Q's refusal to be bothered to pay Fuller's fees for his attendance during the last seven years of his life. Fuller was told not to trouble him with accounts, but to recover his charges from the executors, as there would be plenty of money to pay all bills. On Old Q's death Fuller submitted an account of £12,000. The executors did not consider this sum excessive, but thought that it would be best for the case to be brought before the courts, as at that time an apothecary could only charge for the medicines and appliances supplied and not for his attendance. The friendly action resulted in Fuller receiving a sum of £7500. John Fuller died in 1818 and was succeeded in the practice by his son, Henry Peter Fuller, who was a benefactor to St. George's Hospital, and after whom the Fuller ward in that institution is named. He was visiting apothecary to the hospital for many years, as were his son and grandson. He died in 1866, aged 81. To him succeeded his son William Fuller, who took as partner the late F. B. Manley Sims, and shortly before William Fuller's death the subject of this notice joined the firm.

Henry Roxburgh Fuller was born in 1855. He was the son of Dr. H. W. Fuller, physician to St. George's Hospital, and his wife, Emma, daughter of David Roxburgh. He was educated at Eton and Caius College, Cambridge, and received his medical training at St. George's Hospital, where he was house surgeon and resident obstetric assistant. He took the M.B. in 1883, and in the following year joined his uncle and Manley Sims in the historic family practice. In 1886 he proceeded to the M.D. Camb. For some years he was physician-accoucheur to the St. George's (Hanover-square) Dispensary, and as already stated visiting apothecary to St. George's Hospital. Among his patients was H.R.H. the late Duke of Cambridge. The house in Piccadilly, where the Fullers had for so long practised, was pulled down some 40 years ago, and Roxburgh Fuller removed to Curzon-street, where he practised until his retirement.

MUCH regret is felt in Dublin at the death, at the early age of 27, of ANDREW RICHARD JOSEPH DUNGAN, M.D., lecturer in medical jurisprudence in University College, and pathologist to the Mater Misericordiæ Hospital. Having taken his medical degrees at the National University of Ireland in 1923, Dr. Dungan spent some time in America doing research work in biochemistry, and he subsequently studied at Vienna. Since his return to Dublin he had engaged in research work in pathology and biochemistry, and had made several valuable communications to the Royal Academy of Medicine in Ireland, of which he was a Fellow. His communications were marked by thoroughness, originality, and clearness. He was regarded as a young man of great ability and promise, and his early death is a serious loss to the Dublin School of Medicine. Personally he was held in great affection by his friends and colleagues.

Dr. JOHN NOBLE, one of the best-known practitioners in the Birkenhead district, where he had been in practice for over thirty years, died at his home at Rock Ferry on March 2nd at the age of 67. An Edinburgh man, he studied at the University there and graduated M.B. and C.M. in 1884. In 1907 he went to Birkenhead as partner of the late Dr. Robson, of Rock Ferry, subsequently succeeding to the practice. He was a keen sportsman and promoter of outdoor sports, and did much to stimulate bowling and cricket clubs in the district. During the war he was in charge of the Abbotsford Hospital at Rock Ferry and received the M.B.E. in recognition of his services. For many years he was medical officer of the school ship *Conway*, which is moored in the Mersey. Dr. Noble leaves a widow and two sons.

THE death of Dr. WILLIAM HENRY GRIFFITH, of Chester, occurred on March 8th, in his sixty-first year. Born at Meliden, North Wales, he was educated

at Menai Bridge Grammar School and at Bangor. Proceeding to Edinburgh, he studied medicine in the extra-mural school, at the old Minto House, and College of Surgeons, qualifying as L.R.C.P. and L.R.C.S. in 1894. For a short time he practised at Prestatyn and was a member of the first urban council there. He went to Chester about 29 years ago and was a member of the Chester Council for 26 years, being elected alderman in 1921, when he also filled the office of mayor. Dr. and Mrs. Griffith lost their daughter, an only child, about six weeks ago.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

LOCAL GOVERNMENT (SCOTLAND) BILL.

THE Report stage of the Local Government (Scotland) Bill was concluded in the House of Commons on Wednesday, March 6th.

Mr. HARDIE moved to omit Clause 68, which provides that "if any difficulty arises in bringing into operation any of the provisions of this Act the Secretary of State may by Order remove the difficulty, or do any other thing which appears to him necessary or expedient for bringing the said provisions into operation."

Sir JOHN GILMOUR (Secretary for Scotland) said that he had several amendments to the clause on the paper which would bring it into conformity with that of the English Bill. He agreed that it would be very undesirable that the powers of the Secretary of State should be so expanded as to become an instrument in the hands of the Minister or officials of his department to defeat the considered and determined view of Parliament. But some discretionary power must be left to the Minister.

At a later stage Sir JOHN GILMOUR moved the amendments to which he had referred, the effect of which was to make the first two subsections of the clause read as follows :

(1) If any difficulty arises in bringing into operation any of the provisions of this Act, the Secretary of State may make such Order for removing the difficulty as he may judge necessary for that purpose, and any such Order may modify the provisions of this Act so far as may appear to the Secretary of State necessary for carrying the Order into effect ;

(2) The Secretary of State may make any adaptations or modifications of the provisions of any Act necessary to bring those provisions into conformity with the provisions of this Act.

The clause was also amended to provide that an Order should not be made after Dec. 31st, 1931.

On the conclusion of the report stage the Bill was recommitted, and on the motion of Major ELLIOT (Under Secretary for Scotland) a new clause was added to the Bill enabling the pension of a sick person under treatment in a poor-law institution to be continued without limit of time.

A second new clause which was added to the Bill read as follows :—

It shall be lawful for any county council or for the town council of a large burgh to incur expenditure in making contributions to the central council or committee of an organisation approved by the Department of Health which provides services of the nature of publicity or educational propaganda for any purpose relating to public health, or in the provision by themselves of such services.

The Third Reading Debate.

In the House of Commons on Monday, March 11th, Sir JOHN GILMOUR (Secretary for Scotland), in moving the third reading of the Local Government (Scotland) Bill, said that with the very best intentions many of the existing local authorities had been incapable of meeting the problems connected with housing and public health matters adequately. Unless there was a coördination of effort there would be wastage and inefficiency. In Glasgow, for instance, he did not see that measure of coördination and coöperation between either the private hospitals or the private hospitals and the public hospitals which was essential if there was to be real efficiency. The provisions of this Bill held out, not only the hope but, in his judgment, the certainty of a great solution of this problem. They had behind them the whole-hearted coöperation of the managers of the great hospitals and of the members of the medical profession who were closely linked with them. In the development of these services he visualised more and more paying wards within the hospitals and the building of annexes in the fresher and purer air of the countryside, to which would be taken at various stages those who first entered the hospitals in the great cities. It was only by complete coördination between the work in the city and the local authorities in the counties outside that they would get a proper solution of this problem. If the Bill had dealt with no other problem than the improvement and coördination of the medical services he would have been proud to have introduced it.

Mr. JOHNSTON, in moving the rejection of the Bill, said that it was with genuine regret that they saw in the measure the disappearance of a training ground for public administration in the form of the small burghs of Scotland. He hoped it would be explained in Scotland that the Government were giving no relief for hospitals, but were giving relief for distilleries ; that treatment of venereal disease would be free, but that maternity treatment would be charged for ; and that if an old man who was treated for bronchitis could not pay, his son or daughter could be called on to pay, or, if they could not pay, then his grandson or granddaughter could be obliged to pay.

Dr. DRUMMOND SHIELS, in seconding the motion for the rejection of the Bill, denied that the change from the percentage grant system to the block grant system was a step forward in regard to the public health services. He could not get away from the fact that the impulse for this change came from the Treasury and not from any medical or local government source. Any saving to the Treasury in public health development meant heavier local burdens out of depleted resources, and that was one of the bad things in the Bill ; even maternity and child welfare could not be saved from it. He was more hopeful about the hospital sections of the Bill than any other part of the Bill. The changes that had been made during the Committee stage, although by no means all that they could have desired, had made some progress possible. The distinction between infectious and other diseases could not be justified, and they could only hope that the local authorities would use their discretion wisely in exercising their powers to enforce payment. Many of the people requiring treatment were already harassed by rent and other obligations ; they needed more money when they were ill rather than to incur new penalties. He regretted especially in this connexion that the Government had not seen their way to exclude maternity hospitals. Presumably there would be paying and non-paying wards in the municipal hospitals, just as there were already in many voluntary hospitals. The voluntary hospitals had reluctantly agreed to the new arrangements, but some of their managers and supporters, and certain eminent members of the medical profession, had been voicing their fears of extinction by the municipal hospitals. No one would deny that splendid work which had been done, and was still being done, by the voluntary hospitals. If it was looked at rightly the new development was not a censure on voluntary hospitals, but was a real triumph of their educational work. They had convinced the community that medical and surgical aid must be promptly and fully available to every member of the population. The voluntary system admittedly could not achieve this, and the community therefore must accept the responsibility. For many years to come there would be need of all the resources of both voluntary and municipal hospitals as there was a very big leeway to make up ; and even if municipal general hospitals ultimately met a large part of the demand there was still abundant pioneer work for voluntarism to do. The public conscience was still dull in regard to crippled children for example, 75 per cent. of whom could be made self-supporting if they were earlier treated. Yet they were languishing in hospitals and private homes throughout the country, a burden and an unhappiness to themselves, and very often a burden on the community. Mental defectives were still largely untouched by any kind of organisation. Rheumatic children, who became very often permanent invalids, were in many cases without any treatment of any kind, or any opportunity of getting it. It was well known that the blind and deaf were also a class who had not yet received the attention which their condition and need warranted. He hoped, therefore, that no dog-in-the-manger policy would attempt to hamper the new municipal and county efforts to do the barest duty to the community. He hoped that the inquiry to which Sir J. Gilmour had referred would not be of a vexatious kind, and would not be such as to hamper the local authority or to mulct them in great costs in endeavouring to meet the medical needs of their people. He agreed that there were difficulties in regard to the coöperation of the voluntary and municipal hospitals, in regard to staff, medical teaching, and many other matters, but that could be surmounted by a spirit of goodwill, which he trusted would be forthcoming.

Reply to the Debate.

Major ELLIOT (Under Secretary for Scotland), replying to that debate, said that he had as much knowledge perhaps of the hospitals and their waiting-lists as almost any Member of the House. He had had the compiling of those waiting-lists. He had realised the hope deferred that made the heart sick as week after week and month after month cases came

up asking for treatment where they knew that treatment would be an advantage, but owing to the shortage of accommodation they were forced to deny it. They were going a great way to remedy that situation by the proposals of this Bill. The Mackenzie Committee reported that no fewer than 700 beds of the first class could be made immediately available if accommodation were arrived at between the municipal and poor-law authorities and the voluntary hospitals, and that it would be possible to bring hundreds of beds immediately into service in Glasgow alone. In Aberdeen it had been possible to bring 160 beds into use and keep them constantly filled. They could do that and even more in other cities under this Bill.

The Bill was read the third time by 269 votes to 86.

The Bill was introduced and read a first time in the House of Lords on Tuesday, March 12th.

HOUSE OF LORDS.

WEDNESDAY, MARCH 6TH.

LOCAL GOVERNMENT BILL.

The House went into Committee on the Local Government Bill, the Earl of DONOUGHMORE in the chair.

[The earlier debate on this and the previous day appears on p. 571 of this issue.]

Recovery of Expenses.

On Clause 15, Lord PARMOOR moved to omit the first subsection, which provided for the recovery of the cost of maintenance and treatment in hospitals. He urged that the obligation which the clause imposed upon local authorities was harsh, and that it would prevent the people for whom the hospitals were intended from seeking treatment.

The LORD CHANCELLOR pointed out that the provision of the clause was not that the county council should recover the cost in all cases, but only in those cases where they were reasonably satisfied that the persons liable could afford to pay. He asked their Lordships to reject the amendment.

After further debate Lord PARMOOR withdrew the amendment.

Lord ARNOLD moved an amendment to make the operation of the clause optional instead of compulsory.

The LORD CHANCELLOR said that although the anomalies that would follow as a result of omitting the clause were very great, if this amendment were carried they would be even greater. Payment would be exacted not according to the means of the patients, but according to the generosity of individual councils.

The Marquess of READING thought that it was a pity that the Government should have made the provisions of the clause mandatory.

Lord SEMPILL pointed out that in the Scottish Bill the power to recover was optional, and it passed his comprehension why it should be optional in one measure and compulsory in another.

The LORD CHANCELLOR said he could not see why the clause should be a deterrent to people going for hospital treatment. The Government thought that the right test of the obligation to recover should rest on the ability to pay.

The Bishop of SOUTHWARK and Lord OLIVIER supported the amendment.

The Bishop of WORCESTER thought that public bodies in assessing the sum which was to be paid would only charge what was reasonable.

Viscount KNUTSFORD pointed out that the voluntary hospitals had no power to recover the expenses of treatment. In London alone, however, 500,000 working men subscribed 13*s.* a year so that when they did go into hospital they might be able to pay voluntary contributions. He could not conceive why some such scheme of assurance should not be applied to the new hospitals—namely, that if people went to them for treatment they should pay unless they were already insured persons.

Lord DAWSON said that as he understood the intention of this clause the word "shall" was meant to compel the county council to consider whether if a person was given hospital treatment he was able to pay. If he could not pay it was in their power to relax payment to such extent as they thought fit. By maintaining the word "shall" the Legislature kept control over the question of policy. He thought it was right for the Legislature to retain its power over local authorities. It was well known that there were certain public bodies in this country who believed in free treatment, just as they believed in free education. If free treatment was a right thing—and that was open to argument—it was a policy which should be determined by the Legislature.

The amendment was rejected by 85 votes to 29.

Definition of Infectious Diseases.

Lord ARNOLD moved an amendment which was designed to secure a better definition in the Bill of what were infectious diseases. The clause as drafted was, he said, ambiguous and unsatisfactory. It would be well, he thought, if the Bill definitely stated what were the diseases in respect of which patients, or those liable for their maintenance, would not be liable for payment. They were, for instance, venereal disease, tuberculosis, and cancer. Venereal disease was accepted as an infectious disease. Of tuberculosis there were two kinds, ordinary and surgical. The former might be deemed infectious, but would surgical tuberculosis come within the same category? In no sense, he thought, could cancer be regarded as infectious, but at the same time in the interests of those suffering from cancer, as well as in the interests of the public, they ought to be treated properly and should not be deterred from entering institutions at the earliest possible moment. He hoped that on the Report stage the Government would be able to define exactly what was meant in the clause by infectious disease.

The Earl of ONSLOW said that venereal disease and ordinary tuberculosis would be treated as infectious diseases, but he could not at the moment say whether surgical tuberculosis would come within that category. He would consider before the Report stage whether it would be possible to adopt Lord Arnold's suggestion of including in the Bill a list defining infectious diseases.

Lord DAWSON said he was very grateful to Lord Arnold for raising this matter, for it provided a very fair example, which he hoped would impress the mind of Lord Onslow, of the importance of having doctors who spent their lives looking after curable disease associated in some way with the medical officer of health from the very moment the local authorities undertook these difficult questions. It proved the point he (Lord Dawson) had tried to raise on the previous day. Turning to Lord Arnold's point about tuberculosis, Lord Dawson said that it would be impossible to draw up a list of what the medical profession regarded as infectious diseases, because knowledge was ever growing, and they might put something in the Bill that day and find that they had to bring in an amending Bill next year. The present opinion would certainly be that there were a large number of cases of tuberculosis which were not in any way dangerous to the health of others. They might be very distressing to the children who suffered from them, and to their parents because of the length of the treatment required, but there were many cases of surgical tuberculosis where the danger of the transmission of the disease to others was a very small one. The same might be said with regard to cancer. The prevailing opinion at the moment was that cancer was not an infectious disease. He was afraid that the words "any serious disease" in Lord Arnold's amendment might be made to include the greater part of the diseases which were treated in the hospitals, and therefore they would have the effect, however remote it might be from the intention of the noble Lord, of altering the word "shall" into the word "may." On those grounds he thought that the amendment was impracticable.

The amendment was withdrawn.

Contributions to Maintenance.

Lord COZENS-HARDY moved to insert at the end of subsection (1):—

"Provided that where there is an association or fund for the support of hospitals or the like any such council or local authority may make agreement with such association or fund that if such association or fund pays to the council or local authority an agreed charge in respect of any inmates entitled to benefits from such association or fund the council or local authority shall not exercise its powers of recovery from such inmate or from any person legally liable for his maintenance. Provided further that the council or local authority shall not so agree to any charge which in its opinion would recover less than the average amount otherwise recoverable from such inmates."

He said that the amendment was intended to help the practical working of those associations with weekly contributions from employers and workmen which had done so much to relieve the financial anxieties of many of the voluntary hospitals. It was usual in those cases to provide that if the contributor was in one of the hospitals concerned no charge should be made for his maintenance, but it was not an infrequent occurrence that a contributor was unable to wait for a bed in a voluntary hospital and had in consequence to go into one of the poor-law institutions; and in such cases it had been found that the contributor certainly expected the fund to repay to him any costs that might have been recovered by the local authority from him for his maintenance. When the poor-law hospitals passed over to the local authorities it was probable, and it was to be hoped, that greater use would be made of them, for the number of these cases was likely to increase. As the Bill stood the local authority was bound to consider the case of each inmate separately—a process which involved the annoyance and the trouble of separate inquiries as to financial circumstances, and a separate collection of a large number of separate charges. The amendment aimed at avoiding all that by empowering the local authority to arrange with the managers of a contributory scheme to collect from the fund a sum equivalent to

that which they would on the average have recovered from the individual contributors.

The Earl of ONSLOW said that the amendment raised a point on which he would not like to offer an opinion without a little further consideration. Therefore he suggested that they should postpone the matter for consideration on the Report stage.

The amendment was withdrawn.

An amendment moved by Lord BALFOUR OF BURLEIGH was agreed to, requiring that town planning schemes should be prepared by Jan. 1st, 1934, or such later date before Dec. 31st, 1938, as the Minister in any case might allow.

THURSDAY, MARCH 7TH.

Supervision of Midwives.

On Clause 57 (Supervision of Midwives), the Earl of HALSBURY moved an amendment to provide that the supervision of midwives should be vested in the county councils instead of in the district councils as provided in the Bill. He said if midwives were put under very small areas their work would certainly take them outside those areas, and they would find themselves under a dual control. The effect would probably be that there would be conflicting rules and regulations made by the two bodies, and the rules regarding disinfection might vary in two different areas. It would therefore be better that they should remain under the larger area. He had read through the part of the Royal Commission's Report dealing with maternity and the question of midwives, and he claimed that his amendment would not be at variance with the findings of the Royal Commission. If the district were that of the local education authority, it would be a district of some size. That undoubtedly would please those who advised the midwives, and who in this matter comprised practically every well-known body concerned with midwifery. The larger the area the broader the view, and the less likelihood of local difficulties being put in the way—such a difficulty as that of a doctor preferring one particular midwife because he was working with her, and employing her to the exclusion of others. Furthermore, it would be much easier to get an experienced inspector for the larger than for the smaller area. They were entitled to look at what had happened in the past. Under the Midwives Act, 1902, there was a power for counties to delegate the inspection of midwives and the general question to a smaller committee. Ten counties adopted that, but after trial every one of them gave it up. In 1909 it was suggested by the Departmental Committee that that delegation to small committees should be given up entirely, and it was repealed by the Midwives Act, 1918. Therefore it was not unreasonable to propose that this suggestion might be considered again before this part of the Bill was passed. He had a further amendment which proposed that if there was any difference between the county council and the district council with regard to a possible Order which might be made by the Minister in accordance with this clause, the Minister should hold a local inquiry into the circumstances.

Lord PARMOOR in supporting the amendment said that transference to the smaller authority would be a mistake. He had before him a document showing that the Incorporated Midwives Institute and every other similar association, was opposed to this provision. The later amendment concerning a local inquiry was a very important safeguard.

Viscount KNUTSFORD said he was authorised to state that the Central Midwives Board and Queen Victoria's Jubilee Nurses objected to this transfer of the powers of the inspection of midwives from the county council to a district council. The Incorporated Midwives Institute and the College of Nursing also opposed it. It was essential to encourage women to join the profession of midwifery. It was not easy to get them, and one thing that would make midwives more happy in their work was that they should feel safe that their supervision should be in the hands of someone who knew how to carry out the duties they had to perform, and the standard they had to work up to. They felt certain they could get better treatment and better supervision from the more important body, the county council, than from a district council.

Lord HUNSDON said that the ladies associated with maternity and child welfare work in Hertfordshire viewed the clause as it stood with something akin to dismay.

The Earl of ONSLOW said the very careful provisions of this clause were based on the recommendations of the Royal Commission. The larger municipal boroughs had felt that they had some cause for displeasure because this duty had been taken away from them. It was to be remembered that under the Act of 1925, which was based upon the first report of the Royal Commission, the size of a county borough was increased from 50,000 to 75,000. Therefore there were a large number of towns approaching the 50,000 limit which would have to wait a long time before there was any hope of their becoming county boroughs. It was to such towns more than others that this particular clause was directed. He did not think it was likely, seeing the careful wording of the clause, that any Minister would transfer the supervision of midwives to any authority unless he was perfectly certain that it would carry out the duties well. The clause was very carefully drawn, and he did not think that the interests of the midwives were likely to be injured by its provisions.

After further debate,

The Earl of ONSLOW said it was clear from the speeches that had been made that there was a great desire for the further consideration of this clause. He suggested, therefore, that they should leave the matter as it stood and allow him to consider with the Minister of Health whether it would be possible to meet the wishes of their Lordships. The matter would be brought up again on the Report stage.

The amendment was withdrawn.

FRIDAY, MARCH 8th.

Discontinuance of Grants.

On Clause 78, Earl BUXTON moved an amendment to exclude grants for maternity and child welfare from the operation of the clause. He said the present system by which a local authority which instituted or enlarged or improved its maternity and child welfare centres received a pound-for-pound grant from the Treasury had proved an enormous stimulus to local authorities. The expenditure on these services had risen in the last few years from £12,000 to over £1,000,000, and the numbers had increased from about 400 to 2634. Under the block grant system proposed by the Bill he thought the local authorities would be discouraged in further extensions and improvements of this important social work.

The Bishop of SOUTHWARK said that this part of the Bill had caused great anxiety among people engaged in maternity and child welfare work. The percentage grant system had worked admirably, and it would be unfortunate to make any change. If the health of the mothers and children was to be properly cared for, there would have to be a great extension of this social work. No doubt many local authorities would encourage the work, but there were others who regarded it with suspicion, and naturally they would be loth to take any steps which would involve increasing their rates.

Lord BUCKMASTER said that the maternal mortality in this country was a disgrace, the ratio compared with that of Holland and Sweden being something like 14 to 2. There was not a medical man who would not tell them that the rate of mortality in childbirth was almost entirely preventible . The reasons for the high rate were ignorance and carelessness. It was only by the continued energetic work of the maternity and child welfare centres that the rate of maternal mortality could be reduced and the health of the children improved. The Bill would rob the good work of its incentive to grow.

The Earl of ONSLOW said they were all agreed on the necessity for maintaining and increasing this important social work, and rendering the centres even more efficient. The amendment would, however, fundamentally alter the Bill, because it would cut into the roots of its financial provisions. It would destroy the principle which the Government deemed better than the system of percentage grants. He did not deny that percentage grants were a stimulus in this work. but they were a stimulus in rich areas. Obviously in a rich district there was more money to be spent, and every pound spent meant another from the Treasury. But that was not the case in the poor areas, where these services were most needed. The Minister had ample powers to bring pressure on a local authority which in his opinion was not adequately supporting this essential work.

The amendment was negatived.

Application of the Act to Exceptional Areas.

On Clause 123, which empowers the Minister of Health to make such Orders as he may judge to be necessary if any difficulty should arise in connexion with the application of the Act to any exceptional area, and to modify the provisions of the Act as far as he considers that to be necessary for carrying the Order into effect

Lord ASKWITH moved an amendment to provide that every Order made by the Minister "shall not be of any effect unless and until a resolution affirming the Order is passed by each House of Parliament."

The LORD CHANCELLOR said that this clause was one which was to be found in some shape or form in a good many recent Acts of Parliament, and it had been proved to be very necessary. But he recognised that, as the clause allowed for the possibility of a modification of the provisions of the Act, it might be advisable that the special attention of Parliament should be called to any Order that was made. He could not accept the amendment in the form in which it had been moved, but he was willing to propose that any Order which was made by the Minister in exercise of the power given in

Clause 123 should be brought to the special attention of Parliament instead of being merely laid on the Table of both Houses, and that there should be a necessity for its confirmation by a resolution of each House of Parliament. An amendment would be brought up on the Report stage to deal with the matter.

The amendment was withdrawn.

The Committee stage of the Bill was concluded, and the Bill was reported with amendments to the House.

TUESDAY, MARCH 12TH.

The Age of Marriage Bill.

The Age of Marriage Bill, introduced by Lord BUCKMASTER, the object of which is to make void marriages between persons under the age of 16, was on the motion of Lord Darling referred to a Select Committee.

HOUSE OF COMMONS.

WEDNESDAY, MARCH 6TH.

Mental Patients.

Mr. DAY asked the Minister of Health the number of lunatics in county and borough asylums, hospitals, or licensed houses at the last convenient date.—Mr. CHAMBERLAIN replied: The number of insane patients on Jan. 1st, 1929, in county and borough mental hospitals, registered hospitals, and licensed houses in England and Wales was as follows: In county and borough mental hospitals, 115,690; in registered hospitals, 2,034; in licensed houses, 2,615; total, 120,339.

THURSDAY, MARCH 7TH.

Dangerous Drugs in India.

Mr. GARDNER asked the Under Secretary of State for India if he would give particulars as to the constitution of the Board of Revenue set up by the Government of India to examine applications for permission to import dangerous drugs into India.—Earl WINTERTON replied: The Central Board of Revenue, which has now been appointed by the Government of India to be the competent authority for the purpose referred to by the hon. Member, was constituted in 1924 under the Indian Central Board of Revenue Act, 1924, for the discharge of various administrative functions relating to income-tax, customs, salt, opium, excise, and stamp duties. The Board, which is appointed by the Governor-General in Council, consists at present of two members.

Lost Insurance Cards.

Sir GEORGE JONES asked the Minister of Health whether seeing that a contributor to the national health and pensions insurance, if he lost his card, must replace the card by stamping a duplicate card for any weeks for which the original card was stamped by his employer, he would, in cases where it could be established by unimpeachable evidence that the lost card had the employer's stamps upon it, arrange for a duplicate card to be issued without the contributor having to go to any expense for stamping.—Mr. CHAMBERLAIN replied: I regret that I cannot adopt my hon. friend's suggestion, as it is essential for the proper working of the health insurance scheme that nothing should be done which might conduce to laxity on the part of insured persons with regard to the care and surrender of their cards.

Medical Examination of Female Aliens.

Lieut.-Commander KENWORTHY asked the Home Secretary what medical examinations were made of women and girls entering British ports from France; under what regulations these examinations were made, and in what cases; if he was aware that there had been indignation in France over the alleged humiliating nature of these examinations in certain cases; and whether he would cause inquiries to be made.—Sir W. JOYNSON-HICKS replied: The Aliens Order, 1920, provides that leave to land in the United Kingdom shall not be given to an alien if a medical inspector certifies that for medical reasons it is undesirable that the alien should be permitted to land; and for the purposes of the Order medical inspectors are appointed by and act under instructions issued by the Minister of Health, with the concurrence of the Secretary of State. Legally every alien, whether arriving from France or elsewhere, is liable to medical examination, but in the absence of special reasons it is the practice only to examine those who propose to stay for a considerable period, and in the case of women and girls the examination, at which a nurse or female attendant is present, is usually of a superficial character. As soon as the complaints appeared in the public press, I caused the fullest inquiries to be made into the matter, in consultation with my right hon. friend the Minister of Health. Responsible officers of the two departments visited the ports, and as the result of their investigation they reported that they could find no foundation for the allegation that the examination of women and girls was of a kind that could be regarded as humiliating. I may perhaps add that there is no examination of women for venereal disease. I am anxious to remove any possible source of friction, and I am considering with my right hon. friend what, if any, modification of the existing instructions might usefully be made.

MONDAY, MARCH 11TH.

Sick Leave among Women Clerks.

Mr. KELLY asked the First Lord of the Admiralty the average number of days of sick leave per head during each of the last three years in the case of women clerical officers, writing assistants, and members of the established typing grades respectively, employed in his department; and what was the average number of days of sick leave per head in the case of each of the grades concerned taken on account of gastric or nervous trouble respectively.—Lieut.-Colonel HEADLAM replied: The average number of days of sick leave per head during the last three years in the case of women clerical officers, writing assistants and members of the established typing grades is as follows:—

	Year ended Jan. 31st.		
	1927.	1928.	1929.
Clerical officers ..	7·0 (*a*)	8·7	8·9
Writing assistants ..	8·5 (*b*)	9·7 (*c*)	5·4
Established typing grades	9·9	8·5 (*d*)	10·7 (*e*)

(*a*) Excluding one woman who had 142 days' sick leave. (*b*) Excluding three women who had 276, 144, and 102 days' sick leave respectively. (*c*) Excluding two women who had 171 and 138 days' sick leave respectively. (*d*) Excluding three women who had 206, 117, and 100 days' sick leave respectively. (*e*) Excluding three women who had 137, 132, and 107 days' sick leave respectively.

Colonel Headlam regretted that he was unable to give the information asked for in the last part of the question.

Mr. KELLY asked the Secretary of State for Air a similar question.—Sir S. HOARE replied: The following table gives the information requested in the first part of the question:—

	Average number of days sick leave per head.		
	1926.	1927.	1928.
Women clerical officers ..	15·9	14·0	14·8
Writing assistants ..	18·0	10·6	16·8
Established typing staff ..	13·1	16·7	14·2

To furnish the information requested in the last part of the question, he said, would involve the scrutiny of some hundreds of medical certificates, and he did not think that the labour involved would be justified.

Deaths from Small-pox.

Mr. GROVES asked the Minister of Health if he would investigate the circumstances attending the statement of the chief medical officer that the number of deaths from small-pox in the first half-year of 1928 were given as 37; and whether he was aware that conflicting figures had been given.—Mr. CHAMBERLAIN replied: The figure of 37 deaths from small-pox in the first half-year of 1928, given in the chief medical officer's annual report for the year 1927, were, as explicitly stated in the report, provisional and before complete returns were available. The figure was based upon a system of classification set out in the report.

Deaths from Post-vaccinal Encephalitis.

Mr. GROVES asked the Minister of Health how many cases of and deaths from post-vaccinal encephalitis had been reported to his department since September, 1927, when the Rolleston Committee on Vaccination ceased taking evidence.—Mr. CHAMBERLAIN replied: During the period from Oct. 1st, 1927, till Dec. 31st, 1928, 65 cases in which symptoms suggestive of disease of the central nervous system following within a month of vaccination have been brought to the notice of my department. Of these cases, 32 were fatal. All cases of this kind are reported to the Departmental Committee, but I am not yet able to say how many of these 65 cases are regarded by the committee as cases of encephalitis following vaccination.

TUESDAY, MARCH 12TH.

Definition of Tuberculosis as Infectious Disease.

Dr. VERNON DAVIES asked the Minister of Health if any other form of tuberculosis, except tuberculosis of the lungs, would be regarded as an infectious disease under the Local Government Bill.—Sir KINGSLEY WOOD replied: My right hon. friend is advised that any form of tuberculosis is an infectious disease for the purposes of Clause 15 of the Local Government Bill. As my hon. friend is aware, tuberculosis is expressly excluded from the definition of infectious disease for the purposes of Clause 58 of the Bill.

The Services.

ROYAL ARMY MEDICAL CORPS.

Col. H. Ensor, late R.A.M.C., has been selected for promotion to Major-General, and for the appointment of Deputy Director of Medical Services, Eastern Command, in succession to Maj.-Gen. W. H. S. Nickerson, V.C., who is placed on the Half-pay List

Lt.-Col. T. B. Unwin, having attained the age for compulsory retirement, is placed on retd. pay.

Lt.-Col. J. M. B. Rahilly retires on retd. pay.

Majs. to be Lt.-Cols.: G. H. Richard, vice Lt.-Col. T. B. Unwin, and W. G. Maydon, vice Lt.-Col. J. M. B. Rahilly.

ARMY DENTAL CORPS.

Temp. Lt. W. G. Martin, Dental Surg., Gen. List, to be Lt.

REGULAR ARMY RESERVE OF OFFICERS.

Lt. J. N. Leitch, from Supp. Res. of Off., R.A.M.C., to be Lt.

TERRITORIAL ARMY.

Maj. F. E. H. Keogh, having attained the age limit, retires, and retains his rank with permission to wear the prescribed uniform.

Lt. H. E. Suter to be Capt.

INDIAN MEDICAL SERVICE.

Capt. (prov.) C. V. Falvey is confirmed in his rank.

Temp. Capt. Daulat Manghirmal Lala relinquishes his temp. commn.

Lt. S. N. Evans resigns his commn.

COLONIAL MEDICAL SERVICES.

The following appointments have been made: Dr. A. W. Dunn and Dr. E. C. Savona, Assistant Medical Officers, British Honduras; Dr. C. S. Davies, Medical Officer, Kenya; and Dr. C. P. Murray, Medical Officer, West African Medical Staff.

NAVAL MEDICAL OFFICERS' DINNER.

The annual dinner of the Royal Navy Medical Club will be held on April 25th at the Trocadero Restaurant. Further particulars may be obtained from Surg.-Comdr. A. T. Rivers, R.N., Medical Department of the Royal Navy, Queen Anne's Chambers, Tothill-street, London, S.W.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At a congregation on March 9th the following degrees were conferred:—

Sc.D.—Edward Hindle.
M.B. and B.Chir.—G. W. Pimblett and R. G. Apthorpe.
M.B.—W. E. Underwood.
B.Chir.—E. A. E. Palmer.

Mr. N. E. Goldsworthy, Ph.D., has been elected for three years to the John Lucas Walker studentship for the furtherance of original research in pathology.

UNIVERSITY OF SHEFFIELD.—Mr. Vincent Townrow has been appointed lecturer in diseases of the ear, nose, and throat, and Dr. Rupert Hallam lecturer in dermatology.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL.—A course in methods of examination and diagnosis will be held at this hospital on certain afternoons between April 10th and 26th.

POST-GRADUATE COURSE ON PÆDIATRICS.—An Easter course on New Views in Pædiatrics will be given at the Hôpital des Enfants Malades, 149 rue de Sèvres, Paris from April 3rd to 13th, under the direction of Prof. Nobécourt. Applications should be sent to the secretary of the Paris Faculty of Medicine.

BAYLISS-STARLING MEMORIAL SCHOLARSHIP.—The University College Committee will award in June a Bayliss-Starling Memorial Scholarship of the value of about £120, with exemption from tuition fees. The scholar will be required to follow a course of study involving a training in the principles and methods of research in physiology and/or biochemistry. Application must be made before May 15th, and information may be had from the Secretary of University College, Gower-street, London, W.C.1.

THE KING has conferred the decoration of the Royal Red Cross (second class) on Miss Rosina Davies, of the London Hospital Nursing Staff, "in recognition of devoted service rendered by her" during His Majesty's illness. The first class of this decoration is reserved for nurses on active service.

WEST LONDON POST-GRADUATE COLLEGE.—The fortnight's course at this College from March 11th to 23rd has been postponed until after Easter, owing to the preoccupation of practitioners with influenza.

INDUSTRIAL NURSING.—An Industrial Nursing Conference has been called by the Industrial Welfare Society and will be held at the Hotel Metropole, London, on April 19th. On the following day visits will be paid to factory clinics.

ROYAL SANITARY INSTITUTE.—On Thursday, March 21st, at 3 P.M., Sir Humphry Rolleston will lecture at this Institute, 90, Buckingham Palace-road, London, S.W., on Industrial Disease and its Prevention.—At a sessional meeting at Birmingham on Friday, April 5th, discussions will be opened by Dr. H. P. Newsholme on Coördination and Coöperation in Preventive Medicine, and by Mr. H. H. Humphries on Some Drainage Problems of Birmingham.

METROPOLITAN ASYLUMS BOARD.—Mr. L. F. Hewitt, Ph.D., has been appointed biochemist at the Board's antitoxin establishment at Sutton. He is at present Gibbons Research Fellow at the London Hospital, where he has also held the Freedom Research Fellowship. Previously he held research appointments under the Medical Research Council and at the Hospital for Sick Children, Great Ormond-street.

NORTH-WESTERN TUBERCULOSIS SOCIETY.—At 3.15 P.M., on Thursday, March 21st, Sir Farquhar Buzzard, Regius professor of medicine in the University of Oxford, will give an address to this society in the anatomy theatre of the medical school of the University of Manchester. His subject will be Tuberculosis and the Nervous System, and the meeting will be open to all medical practitioners.

ROYAL SOCIETY OF EDINBURGH.—Among those who have recently been elected Fellows of this Society are the following: Dr. Sydney Smith, Regius professor of forensic medicine, Mr. Walter Mercer, lecturer in clinical surgery, and Mr. B. P. Wiesner, lecturer in sex psychology in the University of Edinburgh; Prof. E. W. H. Cruickshank, of the Physiological Department of Dalhousie University, Nova Scotia; Mr. D. K. Fraser, psychologist to the Glasgow education authority; and Mr. Thomas Southwell, lecturer in helminthology in the Liverpool School of Tropical Medicine.

DENTAL BENEFIT COUNCIL.—In connexion with the provision of dental treatment for insured persons as an additional benefit under the scheme of National Health Insurance, a body to be known as the Dental Benefit Council has been set up in accordance with Regulations under the National Health Insurance Act, 1928. It will be charged with the duty of making arrangements for securing a satisfactory service of dental treatment for members of approved societies who are entitled to dental benefit and of exercising, subject to the general responsibility of the Minister of Health and the Department of Health for Scotland, supervision over the administration of dental benefit.

WORK OF THE LONDON HOSPITAL.—Lord Knutsford, the chairman, last week reported to the quarterly court of governors that there were 14,583 out-patients—over 2000 less than last year. The quinquennial appeal has produced £118,000, the sum hoped for being £200,000.

BIRMINGHAM AND MIDLAND EYE HOSPITAL.—During the past year a new operating theatre has been built and equipped in order that operations upon septic cases may be segregated from clean intra-ocular operations. A pathological department has also been provided, and the ticket system abolished.

DEVELOPMENT OF DROITWICH.—The Droitwich Development Corporation, Limited, has acquired the whole of the town of Droitwich, including the High-street, with 300 shops and houses, the three principal hotels, the two existing brine baths, with the exclusive brine rights over 3000 acres, the park, the golf links, and many miles of existing roads which await development. Over £1,000,000 will be spent on new buildings and reconstruction in the town and baths. Droitwich is two and a half hours by train from London, and it is intended to have an all-the-year-round season.

MELTON MOWBRAY WAR MEMORIAL HOSPITAL.—As soon as means permit, an entirely new building is to be erected adjoining the present hospital, which will then be used for administrative purposes.

REBUILDING OF TIVERTON HOSPITAL.—It is proposed to erect a new hospital at Tiverton at a cost of £30,000 to hold 50 beds instead of the 35 of the present building. It is to be on the bungalow principle.

SUNDERLAND ROYAL INFIRMARY.—At the annual court of governors the chairman of the medical board emphasised the recent remarkable increase in surgical work, which is now five times as great as on the medical side. In 1923 there were 2190 operations; last year the number was 3763. The number of operations on the intestinal tract is much larger, and in 1928 there were 335 operations for appendicitis, with only three deaths.

MANCHESTER UNIVERSITY STUDENTS' "RAG."—The Shrove Tuesday rag of Manchester Students has resulted in the collection of £11,542 for the local hospitals, a drop of about £1200 on 1928. The sale of *Rag-Rag*, the students' magazine, brought in £6000, which exceeds last year's amount by £1400. Glasgow students' collection produced £17,000, constituting a record since the annual collection began in 1921. In nine years the Glasgow students have collected £87,400 for the local hospitals.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, March 19th.—5.30 P.M., GENERAL MEETING OF FELLOWS. Ballot for election to the Fellowship. 8 P.M., PATHOLOGY. Annual General Meeting: Election of Officers and Council. Communications: G. R. Cameron: The Pars Tuberalis of the Pituitary. L. F. Hewitt: Hormones of the Anterior Lobe of the Pituitary. G. Lenthal Cheatle: The Development of Glandular Tissue in Papillomata of the Breast. L. Colebrook: The Cultivation of Spirochæta Pallida in a Tissue-free Medium. Demonstration: D. M. Pryce: The Halo Method of Determining the Average Size of Red Blood Cells.

WEDNESDAY, 8.30 P.M., RECEPTION. From 8.30 to 9 P.M. Fellows and their guests will be received in the Library by the President and Lady Dawson of Penn. At 9.15 P.M., Dr. Leonard Williams will give an illustrated address entitled Napoleon III. Music and light refreshments. Various objects of interest will be exhibited in the Library.

THURSDAY, 4.45 P.M., DERMATOLOGY and EPIDEMIOLOGY (Cases at 4 P.M.). Special Discussion on Industrial Dermatoses, their Causation, Recognition, Prevention and Treatment. Openers: Dr. W. Dyson (Dermatology). Dr. Sibyl Overton (Epidemiology). Other speakers: Dr. Allan C. Parsons, Dr. Howard Mummery and others. 8.30 P.M., UROLOGY, PATHOLOGY, and THERAPEUTICS. Special Discussion on Urinary Antiseptics. Openers: Dr. Langdon-Brown (Urology). Dr. Cuthbert Dukes (Pathology).

FRIDAY, 4.30 P.M., DISEASE IN CHILDREN. Clinical Meeting at the Royal Free Hospital, Gray's Inn-road, W.C. EPIDEMIOLOGY: No Meeting.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

FRIDAY, March 22nd.—9 P.M., Dr. H. Wordsworth Barber: Dermatology in relation to other Branches of Medicine. (Third Lettsomian Lecture.)

MEDICO-LEGAL SOCIETY.

THURSDAY, March 21st.—8.30 P.M., at 11, Chandos-street, Cavendish-square, W., Prof. Sydney Smith: The Investigation of Firearm Injuries, followed by a discussion.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

THURSDAY, March 21st.—8.15 P.M. (at the Royal Army Medical College, Grosvenor-road, Millbank), Prof. J. W. W. Stephens, and the following, amongst others, will give Demonstrations: Dr. Mary Andrews, Major E. E., Austen, Major H. C. Brown and Dr. W. T. C. Broom, Major S. Elliott, Dr. E. Hindle and A. C. Stevenson. Colonel S. P. James, Colonel W. P. MacArthur, Dr. J. C. Ray, Major D. T. Richardson, Dr. V. B. Wigglesworth.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.

TUESDAY, March 19th.—5 P.M., Dr. R. A. Young: A Medical Review of the Surgery of the Chest. (First Lumleian Lecture.)

THURSDAY—5 P.M., Dr. R. A. Young: (Second Lumleian Lecture).

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

MONDAY, March 18th.—5 P.M., Mr. C. E. Shattock: Specimens Illustrating Disease of the Testis.

FRIDAY.—Prof. Sir Arthur Keith: The Nerve Supply and Movements of the Colon.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, March 18th to SATURDAY, March 23rd.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. Mon., at 5 P.M., Lecture by Mr. H. W. Carson on Pitfalls on the Right Side of the Abdomen. WELLCOME MUSEUM OF MEDICAL SCIENCE, 33, Gordon-street, W.C. Wed., 4 P.M., Demonstrations by Dr. S. H. Daukes: A Consideration of the Various Methods of Drug Administration. The above are free.—ROYAL EYE HOSPITAL, Southwark, S.E. Afternoon course in Ophthalmology. Daily at 3 P.M., Clinical demonstration. Further particulars from the Secretary of the Fellowship.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, March 18th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases Clinics. Operations.

ROYAL SANITARY INSTITUTE, 90, Buckingham Palace-road, S.W.

THURSDAY, March 21st.—3 P.M., Sir Humphry Rolleston: Industrial Disease and Its Prevention.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, March 19th.—5 P.M., Dr. G. B. Dowling: Mycotic Diseases.

THURSDAY.—5 P.M., Pathology Demonstration.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL Gray's Inn-road, W.C.

FRIDAY, March 22nd.—4 P.M., Mr. Gill-Carey: Foreign Bodies in the Food and Air Passages.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, March 19th.—3.15 P.M., Mr. G. G. Penman: Ulceration of the Cornea.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, March 21st.—4 P.M., Dr. Paterson: The Food Requirements of Infants and Methods of Determination.

NATIONAL COUNCIL FOR MENTAL HYGIENE, 78, Chandos House, Palmer-street, S.W.

WEDNESDAY, March 20th.—5 P.M. (at the Medical Society of London, Chandos-street, W.), Sir C. H. Bond: The Mental Hospital of Today.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.

FRIDAY, March 22nd.—3.30 P.M. (at the Royal Hospital), Mr. Garrick Wilson: Surgical Cases.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, March 19th.—4.15 P.M., Mr. W. R. Douglas: The Acute Abdomen.

FRIDAY.—4.15 P.M., Mr. J. Howson Ray: Demonstration of Surgical Cases.

Appointments.

MEDLOCK, C. H., F.R.C.S. Eng., L.R.C.P. Lond., to be one of the Medical Referees under the Workmen's Compensation Act for St. Albans, Barnet, Hertfordshire, and Watford County Courts.

Certifying Surgeons under the Factory and Workshop Acts: BLAYNEY, W., F.R.C.P. Lond., M.R.C.S. (Harrold, Beds.); CARSON, F. S., M.D. Belf., D.P.H. (Barrow-in-Furness); FLETCHER, C. G., M.B., Ch.B. Edin. (Kippen, Stirlingshire); and STEWART, W. L., M.B., Ch.B. Glasg. (Grampound, Cornwall).

Vacancies.

For further information refer to the advertisement columns.

All Saints' Hospital for Genito-Urinary Diseases, 91, Finchley-road, N.W.—H.S. At rate of £100 to £150.

Altrincham General Hospital, Cheshire.—Hon. Physician. Also H.S. £105.

Ashton-under-Lyne District Infirmary.—Res. Surg. O. At rate of £200.

Basingstoke, Hants, Park Prewett Mental Hospital.—Jun. Asst. M.O. £350.

Bedford, Bedfordshire Sanatorium.—Res. Asst. M.O. £400.

Birmingham, Ear and Throat Hospital.—Second and Third H.S.'s. Each at rate of £150.

Birmingham, General Hospital.—Res. Anæsthetist. £120. Also four H.S.'s Each £70.

Birmingham, Queen's Hospital.—Anæsthetist. At rate of £70 to £100. Also three H.S.'s. At rate of £70.

Blackburn and East Lancashire Royal Infirmary.—Res. H.P. £150.

Bristol City Mental Hospital.—Third Asst. M.O. £300.

Cambridge, Addenbrooke's Hospital.—H.S. At rate of £130.

Cancer Hospital, Fulham-road, S.W.—Anæsthetist.

Cardiff, City Mental Hospital, Whitchurch.—Research Chemist. £800.

Chelmsford and Essex Hospital.—Res. M.O. £150.

Chester, Royal Infirmary.—Hon. Asst. Physician.

Coventry, Coventry and Warwickshire Hospital.—Hon. Physician.

Derby, Derbyshire Hospital for Sick Children.—Hon. P. and Pathologist. Hon. Ophth. S. Also Hon. S. to Ear, Nose and Throat.

Doncaster, Royal Infirmary.—Third. H.S. At rate of £150.

Dreadnought Hospital, Greenwich, S.E.—H.P. and H.S. Each at rate of £110.

Dumfries, Crichton Royal Mental Hospital.—Clinical Pathologist. £400.

East Ham Education Committee.—Aural Surgeon. Also Ophthalmic Surgeon. Each 3 guineas per session.

Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Asst. Obstetrician.

Evelina Hospital for Children, Southwark, S.E.—H.S. £120.

Exeter, Royal Devon and Exeter Hospital.—H.P. At rate of £130

Gloucester, Gloucestershire Royal Infirmary and Eye Institution.—Second H.S. At rate of £100.

Hastings, Royal East Sussex Hospital.—Pathologist. Asst. Physician. Also M.O. to V.D. Department.

Hereford, Herefordshire General Hospital.—H.S. £150. Also H.P. At rate of £100.

Hospital for Sick Children, Great Ormond-street, W.C.—Part-time Jun. Cas. O. At rate of £150. Also H.S. and H.P. At rate of £100.

Hull, Sculcoates Union Institution, Beverley-road.—Non-Resident Sen. M.O. £700.

Inverness Royal Infirmary.—Hon. Surg.

Italian Hospital, Queen-square, W.C.—Hon. Anæsthetist.

Leeds Tuberculosis Sanatorium, Killingbeck.—Asst. Res. M.O. £250.

Leicester Royal Infirmary.—H.P. £125.

Lewisham Hospital, S.E.—Fifth Asst. M.O. £300.

Lincoln County Hospital.—Jun. H.S. At rate of £150.

L.C.C. Mental Hospital Service.—Eighth Asst. M.O. £300.

London Temperance Hospital, Hampstead-road, N.W.—H.P. At rate of £100.

Manchester Babies Hospital, Burnage-lane, Levenshulme.—Jun. Res. M.O. At rate of £50.

Manchester Royal Infirmary.—Res. Surg. Officer. £200.

Mexborough, Yorks, Montague Hospital.—H.S. £120.

Middlesex Hospital, W.—Sen. Res. Asst. Anæsthetist. At rate of £120.

Miller General Hospital, Greenwich-road, S.E.—Hon. Asst. Dental Surgeon.

Newcastle-upon-Tyne, University of Durham College of Medicine.—Asst. in Pub. Health Labs., &c. £350–£450.

Oxford, Radcliffe Infirmary and County Hospital.—Hon. Asst. Surgeon.

Oxford, Wingfield Orthopædic Hospital, Headington.—H.S. £150.

Prince of Wales's General Hospital, Tottenham, N.—Hon. Anæsthetist. £20. Also Hon. Dermatologist.

Reigate Borough.—Medical Officer for Maternity and Child Welfare Centre. £150.

Richmond, Surrey, Royal Hospital.—Sen. H.S. Also Jun. H.S. At rate of £150 and 900 respectively.

Royal National Orthopædic Hospital, 234, Great Portland-street, W. Hon. Asst. S.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Hon. Surgical Registrar.

St. Marylebone General Dispensary, 30, Marylebone-lane, W.—Physician to Dermatological Department.

St. Thomas's Hospital, S.E.—Asst. Surgeon in Orthopædic Dept.

Salisbury General Infirmary.—Two H.S.'s. Each £150.

Salop County Council.—Asst. M.O. £600.

Sheffield, Royal Infirmary.—Surgical Registrar. £200.

West London Hospital, Hammersmith-road, W.—H.P. and Two H.S.'s. Each at rate of £100. Non-Res. H.O. for Children's Department. 5 guineas weekly. Also Hon. Asst. Anæsthetists.

The Chief Inspector of Factories announces a vacancy fo a Certifying Factory Surgeon at Littleport (Cambs.).

Births, Marriages, and Deaths.

BIRTHS.

ALABONE.—On March 6th, at "Brent Tor," Dyke-road, Hove, the wife of Leslie Alabone, L.D.S.R.C.S.Eng., of a daughter.

ELKINGTON.—On March 4th, at Welbeck-street, the wife of Capt. E. H. W. Elkington, R.A.M.C., of a daughter.

GRAY.—On March 5th, at Westerhall, Weymouth, the wife of Adam Gray, M.D. Aberd., of a son.

HUGHES.—On March 5th, at The Mall, East Sheen, the wife of Royston Hughes, L.D.S. Eng., of a daughter.

MARRIAGES.

CRADDOCK—JOYCE.—On March 2nd, at St. Mary's, Paddington, Stuart Craddock, M.B., B.S., M.R.C.S., L.R.C.P., to Lilian Margaret Heath Joyce.

EMERY—STEWART.—On March 2nd, at Regent-square Presbyterian Church, W.C., Clyde K. Emery, B.A., M.D., M.R.C.S., L.R.C.P., to Wendy Stewart, B.Sc., daughter of Dr. and Mrs. A. A. Stewart, of Northampton.

DEATHS.

COOMBS.—On March 3rd, at Bedford, Rowland Hill Coombs, M.D., M.R.C.P., D.L., J.P., aged 84.

DIXON.—On March 8th, at The Bungalow, Stevenage, George Frederick Dixon, M.R.C.S., L.R.C.P., in his seventy-third year.

DOYLE.—On Jan. 29th, 1929, at Sydney, in the seventieth year of his age, The Honourable Henry Martin Doyle of Newcastle, New South Wales, member of the Legislative Council of New South Wales, M.R.C.S. England, L.R.C.P. London, L.S.A. London, youngest son of the late James Doyle of Ballan, Victoria, and of Tombric on the River Slaney, Wexford, Ireland, and nephew of the late Venerable Canon Thomas Doyle of Ramsgrange, Wexford. Born at Ballan, Victoria, 1859. R.I.P.

FULLER.—On March 7th, at Abercorn-place, N.W. Henry Roxburgh Fuller, M.V.O., M.D., late of Curzon-street, W. 1, after a long illness.

KENDALL.—On March 5th, at Chiddingfold, Nicholas Fletcher Kendall, M.R.C.S., L.R.C.P., aged 59.

RIVIERE.—On March 6th, at Queen Anne-street, W. of pneumonia, Clive Riviere, M.D., F.R.C.P., aged 56.

THOMSON.—On March 6th, at Leyborne-park, Kew Gardens, Surrey, Elsie Thomson, M.B., Ch.B. Edin., D.P.H., aged 37 years.

WALKER.—On March 3rd, at Deerfield-road, March, Cambs., James Pixton Walker, M.D., M.R.C.S., L.R.C.P. D.P.H., County Medical Officer, Isle of Ely, aged 63.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

MEDICO-LEGAL DIFFICULTIES IN GENERAL PRACTICE.

AN ADDRESS AND A DISCUSSION.

AT a meeting of the West Kent Medico-Chirurgical Society held on March 8th, Dr. T. E. WHITE, Vice-President, took the chair, and Dr. JAMES NEAL, Secretary of the Medical Defence Union, read a paper on Some of the Medico-Legal Difficulties of General Practice.

During 1928, he said, he had been consulted by over 1400 medical practitioners—which gave some idea of the prevalence of medico-legal problems in the profession. Most of them were preventable; many were due to carelessness or slackness; some to ignorance of the statutes which affected a medical practitioner. The doctor was subject to all the obligations of an ordinary citizen, except jury-service, and even from that he must claim exemption when the lists were revised; if his name appeared on the list he would be liable to serve. In addition, some 50 special statutes imposed duties on the medical practitioner in connexion with his work, and obligations imposed by professional traditions regulated his relations with the public and his colleagues. The General Medical Council was the only authorised body empowered to exercise control over the doctor, and it derived its authority solely from its power to erase a name from the Register. Every practitioner should therefore make himself acquainted with the various pronouncements of the Council.

Obligations of the Registered Medical Practitioner to the State.

Notification of Births.—Too often the practitioner "in attendance upon the mother at or within six hours after the birth of a child," omitted to ascertain whether the father or nurse had given the required notice in writing to the medical officer of health, with the result that—owing to the default of others—he rendered himself liable to a fine. All births after the twenty-eighth week of gestation must be notified, whether the child were born alive or dead. As stillbirths must now be registered, the doctor might be required to certify that the child was not born alive, but this was not a statutory duty and the certificate could be charged for. No charge could be made for notification of birth.

Certification of Death.—The doctor attending a patient in his last illness must sign and deliver to the registrar—either personally or in the official franked envelope by post—a certificate of the cause of death. Notice in writing of the signing of the certificate must be given to the person who would register the death. Even when the doctor desired to refer the facts to a coroner he should not now refuse the statutory certificate, but should indicate on the back thereof that he had reported to the coroner, and the registrar would then suspend registration of death until he learned whether or not the coroner would hold an inquest. The doctor must state on the certificate whether or not he had seen the deceased since death, and the registrar would report to the coroner any case where the deceased had not been seen by the certifying practitioner since death or alive within 14 days before death. No fee could be charged for the statutory certificate, but any additional certificate required by the relatives might be charged for. Any certificate required under the Friendly Societies' Act must be a "certified copy" issued by the registrar and not a duplicate signed by the doctor. The statutory certificate could not be refused on the ground that professional fees were owing.

Inquests.—There was no statute imposing on medical practitioners the duty of notifying a death to the coroner, but the doctor shared with others the common law duty of informing the coroner of any case of sudden or suspicious death. For a post-mortem examination and report ordered by the coroner the practitioner would be paid a fee of two guineas, with an additional guinea if he gave evidence at the inquest. The fee for giving evidence without a post-mortem was one-and-a-half guineas for each day. The doctor should insist on a subpœna for the inquest, as without it he would not be able to enforce his claim for a fee.

Notification of Infectious Disease.—It was the duty of every doctor, on becoming aware that a patient was suffering from a scheduled infectious disease, to send forthwith to the medical officer of health a certificate stating the name of the patient, situation of the building, and the disease. Similar notifications must be sent to the chief inspector of factories in the case of lead, phosphorus, arsenic or mercury poisoning or anthrax contracted in any factory or workshop. It was customary to notify infectious disease by telephone to ensure early removal to hospital, but the statutory written notification should be made at the earliest moment also.

Evidence in Court.—The evidence in court of a medical practitioner was privileged to the extent that no civil action would lie against him in respect of it, but he could not refuse to disclose information obtained in the course of professional relationship. He should appeal to the judge if asked to disclose a confidence, but if the judge directed him to answer he must obey or take the consequences, which might involve committal for contempt of court. The fee for a professional witness in criminal cases was fixed by Home Office regulations. In civil cases the High Court usually allowed from one to five guineas a day with reasonable travelling expenses, but the witness usually arranged professional fees with the solicitors. He should insist on a written undertaking beforehand to pay the agreed amount. It was worth remembering that the only way to avoid the risk of being compelled to attend Court was to avoid being in a position to give evidence on any matter likely to be the subject of legal proceedings. Before giving a report in a case that might lead to litigation it was wise to insist on a written guarantee of fees for the report and for subsequent attendance in Court.

Dangerous Drugs Regulations.—The publication of the Dangerous Drugs (Consolidated) Regulations, 1928, had simplified the complex position relating to dangerous drugs. All doctors were now required to enter in a register true particulars of every quantity of any drug or preparation obtained. Seventeen preparations were specifically exempted, as were also those containing less than one-fifth per cent. of morphine or one-tenth per cent. of cocaine. All strengths of heroin and extracts and tinctures of Indian hemp were now included. A medical practitioner was entitled to prescribe whatever drugs he conscientiously believed to be necessary for the patient, but if he were disposed to order an excessive quantity of a dangerous drug he would be well advised to call in a colleague of repute to assist him in deciding the amount. Administration of morphine or heroin to addicts could only be regarded as legitimate for persons undergoing treatment by gradual withdrawal and for those from whom, after every effort had been made, the drug could not be completely withdrawn. In either case the practitioner should exercise close supervision and share his responsibility with a colleague. Since 1926 special tribunals might investigate the case of a doctor who was believed to be supplying or prescribing the drugs otherwise than in proper medical treatment, and on their recommendation the Home Secretary might withdraw the doctor's authorisation, so that—although still entitled to practise—he would be deprived of a part of his necessary equipment.

Certification.—Medical certification of all kinds bristled with dangers, and scrupulous care should be taken only to certify such facts as were within the personal knowledge of the certifier. Words affecting the character and reputation of the person concerned must not be used. Many certificates were highly confidential and should be handed to the patient only. The diagnosis of an infectious disease might be called in question, but provided the certifying doctor possessed average skill and knowledge and had taken reasonable care, he was not likely to be held liable. A doctor consulted in a case of alleged insanity ought to be protected from the heavy legal costs of defending undeserved attacks or ridiculous accusations. Section 330 of the Lunacy Act, 1890, was clearly intended to afford some measure of protection, but since the case of *Toogood* v. *Wilks* it had been held that the burden of proving negligence did not lie with the plaintiff, but that the doctor must prove that he had acted in good faith and with reasonable care. This particular point, however, had not been made clear by the Court of Appeal in the Harnett case, and where the onus of proof lay was not quite certain. However much it might be possible to strengthen Section 330, there would remain the danger of an action for libel. If the certificate had been given in good faith and with reasonable care this ought not to be possible, for no action would lie if the same statements had been made in the witness-box on oath. At present, however, every certifying doctor had the fear of subsequent litigation in his mind for many years.

The Doctor's Obligations to His Patient.

In every case a medical practitioner was legally bound to employ a reasonable amount of knowledge, skill, and care, and—in the absence of a definite arrangement that he should not be paid—he was entitled to be reasonably remunerated for his services. A doctor was not at the beck and call of anyone who chose to send for him. There was no law to compel a man to attend a patient, but if he once undertook to do so he must not go back, except at his own risk. Even if he were attending a case gratuitously he should only withdraw after giving the patient reasonable opportunity to obtain other medical assistance. The legal relationship between doctor and patient was one of contract, and the contract should be as definite as possible from the

outset, to avoid misunderstanding. When some person other than the patient promised to pay the medical fees, the promise should be given in the presence of a reliable witness or confirmed in writing, and the doctor must be careful in the first place to render his account to the person thus made liable and not to the patient. If the promise were conditional—that the other person would pay if the patient did not—the guarantee must be in writing to render it legal. Parents were liable for the fees of a minor, and the husband was liable for his wife, even when separated, unless she had been guilty of adultery or he had made her a definite allowance to cover the cost of medical attendance. An employer was not usually liable for the fees for his servant unless he had assumed liability by a specific contract. Whoever called in a doctor in an emergency was liable for that particular visit, but not for subsequent ones.

A practitioner had no right to do anything to a patient without his consent, or to a child without the consent of parents or guardians. In emergency he must exercise his discretion. Ideally the surgeon should obtain written authority to use his discretion before operating, or he risked an action for assault. A practitioner should not, without the patient's consent, disclose information obtained in the exercise of his professional duties, but this rule was often very difficult to observe strictly. Chief constables sometimes circularised local doctors asking them to inform the police if they should be called in to a woman recently confined when the child was missing; such circulars should be ignored, for it was not part of a doctor's duties to act as a detective. If a mistress brought her servant to the doctor, he could only examine the girl with her own free consent and could only report to the mistress with the girl's permission. In the absence of conclusive objective evidence of criminal interference the doctor would be wise to regard cases of abortion as natural and to refrain from asking questions or receiving information which would make him an accessory after the fact. Even when convinced that the abortion had been criminal he was under no legal obligation to inform the authorities, but if the patient were likely to die he should as a rule urge her to make a statement which might be used as evidence against the abortionist. A dying declaration need not be in writing, though it should be so if possible, and must be signed by the writer and the patient, and witnessed. The doctor who gave information on the uncorroborated statement of the patient might find himself in serious difficulties. In cases of attempted suicide the main consideration must be the welfare of the patient, and only very rarely should information be given to the police.

No information might be given to a wife or husband without the patient's consent, and the wisest course was to explain the illness fully to the patient and refer inquiries to him. The only exceptions to the rule of professional secrecy were where disclosure was required under an Act of Parliament, as in infectious disease; where it was given in obedience to an order of the Court, and when given to prevent the commission of a crime or grave danger to another, or to safeguard the interests of the patient himself. The doctor must be prepared to justify any departure from the usual rule.

Allegations of Negligence.

However well informed and careful a practitioner might be, he was always at the mercy of any aggrieved person. It was a great temptation to avoid publicity by a small monetary payment, but every case fought and won would help to protect other practitioners from similar claims. Most allegations of negligence were set up as a counter-claim against the payment of fees. If a doctor had exercised due care and ordinary skill he was entitled to be paid; his employment did not imply a contract to cure. Negligence could not be defined; substantially, it meant failure to exercise "reasonable skill and care," and this might include instructions to the nurses and patient for their conduct in the doctor's absence or after his attendance had ceased. Each case must be decided on its merits, and it was rarely possible to appeal against the decision of a jury on a question of fact such as negligence; the bench often displayed a tolerant attitude to the doctor, but it was by no means certain that the jury would do so. It was the easiest thing in the world to trump up a charge against a doctor; almost any line of treatment was open to criticism. The defence depended upon the evidence available to rebut the alleged negligence. The prudent man would therefore adopt precautions as a routine. Detailed examination and elaborate tests were of the greatest value when a case went into court. A stupid error in diagnosis was not likely to lead to disaster if there had been a punctilious observance of all the customary procedures for arriving at a correct diagnosis, but an excusable or almost unavoidable mistake was difficult to defend if there had been an omission of any recognised procedure, however useless in the particular case. Even the most necessary routine examination of a woman might be misconstrued as an indecent assault, and if that risk were carefully avoided the doctor might be charged with incomplete and negligent examination. The peril was no mere bogy. In cases of extreme carelessness or gross ignorance criminal proceedings might be taken against the doctor.

Libel and Slander.—Responsibility of the Surgeon.—Gifts.

Doctors were particularly liable to be prejudiced in their profession by slanderous rumours; it was of paramount importance to get evidence as early as possible and to secure a signed statement from anyone who could testify to the utterance. It was not sufficient to say that "scores of people" had heard the slanders and would be pleased to give evidence when the time came.

In any case of injury to bones or joints the doctor should invariably advise X ray examination, and take some steps to record the fact if the advice were refused. It was generally said that a surgeon was responsible for negligence on the part of his helpers at an operation, but it was very doubtful if he could be held responsible for the acts of, for instance, a fully trained nurse carrying out duties delegated to her, fully within her competency, and which the surgeon could not conceivably supervise while attending to his own work. Apart from midwifery it was extremely indiscreet for a doctor to operate and anæsthetise single-handed; he should never do it on a woman patient. Dr. Neal regarded any sterilising operation—except for pathological conditions—as illegal, and thought that if the patient should die the operator would be in grave danger of conviction for manslaughter.

There must be no possibility of even a suspicion of undue influence on the part of a doctor for his own benefit in the case of gifts and legacies from patient to doctor. Undue influence must be proved in order to invalidate a will and it must be shown that the testator was coerced into doing what he really did not want to do.

Inquiries by Public Health Officers.

Early in 1927 practitioners in four districts had been asked to give information on the health of parents, the character of pregnancy, and any history of tuberculosis, syphilis and rickets, as part of an international inquiry into infant mortality. The Medical Defence Union had been unable to advise compliance with these requests in individual cases, and the form of questionaire had soon been modified, although not so much as to render it unobjectionable. Inquiries had recently been made in connexion with puerperal fever regulations; the objection to these lay in the fear that the information given might prejudice the doctor's legal position in the event of proceedings for alleged negligence. Medical practitioners were under no obligation to furnish any information to the medical officer of health in such cases.

Doctors were frequently liable to a double penalty for a single offence, for any practitioner who had been convicted and punished for a felony or misdemeanour was liable to have his name erased from the Medical Register. The medico-legal dangers of the doctor were by no means imaginary.

Some Points Raised in Discussion.

In reply to various questions put by members of the audience Dr. Neal added the following points:—

In practice it was often inconvenient to post a death certificate to the registrar on account of the delay involved; by law it must either be handed personally or sent in one of the franked envelopes, but the registrar often allowed it to be sent by a messenger—who might be the relative—at the doctor's own risk. If a policeman fetched a doctor for an accident the fee should be recoverable from that individual policeman, but not necessarily from the police force. In some districts the police would always pay; in others they would not. The rule of professional secrecy did not depend upon the severity of the disease. If a contagious syphilitic patient, after full explanation, insisted on marrying, the doctor's action was a matter for his individual conscience. If a mother brought her daughter whom she suspected of being pregnant, the doctor should insist that the daughter tell her mother rather than tell her himself. A doctor who contracted an infectious disease in the course of his employment by a public body could only have a claim against that body either under the Workmen's Compensation Act—the total allowance being then 30*s.* a week—or under common law. Unless there were negligence on the part of the authority he would have no redress. To tell a nurse attending a patient that the latter had, for instance, syphilis, and warn her to be careful, would be a privileged communication and certainly necessary in the interests of the nurse. A hospital was not likely to be liable for the actions of its medical officers if due discretion and care had been exercised in their selection. The guardians would usually pay the expenses of a poor-law medical officer sued for wrongful certification under the Lunacy Act, though not perhaps his damages, if awarded.

There was no doubt that a surgeon would not be held responsible for negligence on the part of the anæsthetist. A remark in the doctor's notes: "X ray advised and refused" would certainly be a valuable defence, especially when the absence of an X ray picture was the only point where negligence was alleged.

THE HEALTH OF PALESTINE AND TRANS-JORDANIA.

A REPORT, signed by Field-Marshal Lord Plumer, the High Commissioner, was recently presented by H.M. Government to the Council of the League of Nations on the administration of Palestine and Trans-Jordania for the year 1927.

Epidemic Disease.

Palestine was comparatively free from epidemics of the more serious diseases. There were 1001 cases of enteric with 76 deaths; the incidence was high in Jerusalem, but much reduced in Haifa, Tel-Aviv, and the Jewish settlements in the Valley of Esdraelon, where inoculation, practised after the serious outbreaks of 1926, gave a large percentage of immunity. Dysentery was more prevalent, with 1782 cases, 31 fatal. Neither plague nor cholera occurred. There was a single case of small-pox in Jerusalem, imported from Damascus; 34,000 inhabitants of Jerusalem underwent vaccination in consequence; the total of vaccinations during the year reached 81,893. There were 3305 cases of measles, a source of considerable infant mortality; 324 deaths resulted. Eighty-three cases of typhus occurred, with one death, in villages where the disease is endemic. Urban scavenging services were generally well maintained and not a few improvements in organisation and in refuse disposal introduced. The improvement in the sanitation of shops and houses was marked in old quarters as well as in new suburbs. A little progress was made in improving the sanitary conditions in the settlements attacked by enteric fever.

Vital Statistics.

The birth-rate was slightly less than in 1926 and the death-rate and infantile mortality increased. There were 3186 more deaths than in 1926, including 2620 of children under 5 and 450 of persons over 50 years. This increase was evenly distributed among Moslems, Jews, and Christians, and is not attributable to infectious disease. For the quinquennial period, 1923–27, the birth- and death-rates per 1000 were as follows:—

	Birth-rate.	Death-rate.	Estimated population.
1923	47·43	25·67	662,013
1924	51·31	25·94	681,245
1925	49·31	27·25	719,508
1926	53·47	24·43	761,896
1927	50·35	28·01	778,369

(NOTE.—No figures, either in this table or the one below, are included for the nomadic Bedouin population, estimated at 103,000.)

The following is a comparative table of births and deaths by religions for the year 1927:—

	Christians.	Moslems.	Jews.	Others.	Totals.
Population ..	76,839 ..	545,225 ..	147,687 ..	8,618 ..	778,369
Deaths	1,545 ..	18,031 ..	1,987 ..	243 ..	21,806
Death-rate per 1000 ..	20·10 ..	33·07 ..	13·45 ..	28·19 ..	28·01
Births	2,991 ..	30,586 ..	5,182 ..	434 ..	39,193
Birth-rate per 1000 ..	38·92 ..	56·09 ..	35·08 ..	50·35 ..	50·35
Deaths of infants under 1 year	560 ..	6,631 ..	598 ..	68 ..	7,857
Infantile mortality-rate ..	187·22 ..	216·79 ..	115·79 ..	153·68 ..	200·46

Personnel.

Twenty-six pupil midwives and 11 midwives with foreign qualifications were licensed, bringing the number of trained and licensed midwives up to 221. Yet midwives are reluctant to settle in the villages to practise among the peasantry where their attendance is a crying need. There are now 561 doctors, 160 pharmacists, and 183 dentists licensed in Palestine. At the end of the year there were 28 child welfare centres—17 Jewish, 7 Government and municipal, and 4 conducted for Arab children.

Leprosy. Malaria.

Twenty-four lepers, who are not in-patients at the Moravian Mission Home in Jerusalem, receive out-patient treatment at the Government dispensaries. A British specialist surgeon has been appointed to the staff of the Department of Health. Improvements at the Jaffa Lazaret are in progress; it is being adapted to receive infectious cases in the event of a large epidemic. The Haifa Lazaret was remodelled and re-equipped to provide good accommodation for 500 persons. 601 Palestinians made the pilgrimage to Mecca. Foreign pilgrims, Persians, "Iraqis," and Indians show an increasing tendency to return by way of Palestine and so overland to Iraq. The cholera epidemic in Iraq necessitated special precautionary measures on the Palestine and Trans-Jordan frontiers, which the rapidly developing trans-desert route from Iraq to Syria and Palestine renders more liable to infection. There was rather more malaria on the whole than in 1926, and during the autumn several sharp but localised outbreaks occurred in the Jordan Valley and other infected regions. An important scheme for draining the malarious Kishon swamps near Haifa at a cost of £P22,000 has begun. The Palestine Jewish Colonisation Association continued work on the drainage of the Kabbara marshes. Malaria control measures over a large area round the Palestine Electric Corporation's camp near the confluence of the Jordan and Yarmuk were carried through by Government agency.

Hospitals.

The Government are contributing some 30 per cent. of the cost of a new hospital in Tel-Aviv, and will guarantee payment of an annual contribution by the Tel-Aviv township towards its maintenance on condition that a certain number of beds is set aside for the treatment of local cases of minor infectious diseases. Two new motor-ambulances have been obtained for the Department of Health; police in each district were instructed in first-aid, and police-stations re-equipped with first-aid materials.

Over 100,000 routine bacteriological and chemical investigations were carried out. The bacteriological subsection of the Government laboratories has produced all prophylactic and curative vaccines required by Palestine and Trans-Jordan as follows: Small-pox, 180,000; plague, 1500; typhoid, 32,600; T.A.B., 38,650; cholera, 60,800; antirabic, 71,585 (1008 treatments). The chemical subsection devoted itself to the analysis of edible oils and fats.

Trans-Jordania.

During the year the following cases of infectious diseases occurred: Of enteric fever, 66 with 6 deaths; of influenza, 34 with 6 deaths; of dysentery, 66 with 2 deaths; of whooping-cough, 31; of measles, 154 with 30 deaths; of mumps, 154; of chicken-pox, 12; of pneumonia, 37 with 7 deaths; of puerperal fever, 4; and of erysipelas, 14 cases with 1 death. There were single cases of small-pox (imported) and diphtheria. The steps taken to protect water-supplies from contamination have noticeably reduced the incidence of enteric and dysentery. The control of malaria throughout Trans-Jordania is well in hand. Special campaigns were organised in the fertile but hitherto infected areas along the south-eastern shores of the Dead Sea, where 88,000 metres of canal and stream were cleared and rendered innocuous. The Italian National Association opened a hospital at Amman with 28 beds. The Church Missionary Society's hospital at Es Salt receives an annual grant of £E240 from Government. The Department of Health has now a laboratory section in charge of a qualified bacteriologist.

BIFOCALS FOR GOLFERS.

UNDER this heading there is a letter in the *Optician* for Feb. 1st in which the writer relates that he was one day playing golf with an opponent who was wearing bifocal spectacles and inquired how he managed to see the ball. "His reply was unexpected. He said he had improved his game at least six strokes a round because the bifocals made him keep his head low." As is well known among golfers one of the most distressing maladies to which they are subject, with which the mere will is often powerless to grapple, is that of "looking up." What actually happens is that at the moment of striking the ball our heads go up while our eyes are still looking down. The suggestion is that if we cannot see the ball clearly through the lower part of our spectacle glasses that will serve as a reminder to us not to move our heads up at the critical moment, with the result of "topping" the ball. The story is one over which medical golfers might do well to ponder, and perhaps to test by experiment.

CLAYTON HOSPITAL, WAKEFIELD.—Miss Elizabeth Childs last week cut the first sod in preparation for the building of the new women's wards at this hospital, the cost of which, approximately £30,000, is being borne by her cousin, Mr. Samuel Childs, of Camden, New Jersey, a native of Wakefield. The new wing will adjoin the out-patients' department, which was recently built and equipped by Mr. Childs. It will comprise two women's wards with 48 beds and a small private ward for paying patients, and will be a complete unit with its own operating theatre.

Lumleian Lectures

ENTITLED

A MEDICAL REVIEW OF THE SURGERY OF THE CHEST.

Delivered before the Royal College of Physicians of London

BY R. A. YOUNG, C.B.E., M.D., B.SC. LOND.,
FELLOW OF THE COLLEGE; SENIOR PHYSICIAN TO THE MIDDLESEX HOSPITAL; PHYSICIAN TO THE BROMPTON HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST.

LECTURE I.

Delivered on March 19th, 1929.

MR. PRESIDENT, CENSORS, AND FELLOWS OF THE COLLEGE,—Curiosity, stimulated by the search for a subject, and by a brief reference in the College List to Holinshed's "Chronicles,"[1] impelled me to delve a little into the early history of the Lumleian lectures. I found that they were the joint foundation of Dr. Richard Caldwell and the Lord Lumley, and were endowed by each equally. Though initiated in 1581, the first series were not given until 1582, when Dr. Richard Forster[2] was appointed lecturer, a post he filled until 1602. The immortal Harvey was appointed lecturer in 1615 and held the post for 41 years. It was through the medium of these lectures that he first published his views on the circulation.

There can be little doubt that the relations between Lord Lumley and Dr. Caldwell were those of professional attendance and friendship, and that the zeal of the latter for the advancement of his profession, backed by his own generosity, stimulated Lord Lumley to a like enthusiasm and practical sympathy. Lord Lumley was a learned man and a member of the Elizabethan Society of Antiquaries. His library was bought by King James I. and eventually given to the British Museum by King George III. He seems to have sympathised with Mary, Queen of Scots, and he languished in the Tower in 1569 and in the Marshalsea in 1571.[3] Though he died on Tower Hill, he was fortunate enough to do so in his own house and with his head on his shoulders, instead of in the adjacent execution ground. His father was both attainted and executed, and the peerage was a restoration to the status of his grandfather.

Dr. Caldwell is referred to in Holinshed as the "English Hippocrates and Galen." He was admitted a Fellow of this College in 1559 and made a censor the same day. He was afterwards President in 1570. It would seem that Caldwell was specially interested in surgery. His one published book, a posthumous publication, was a translation of some "Tables of Surgerie" by Horatius Morus, a Florentine physician. His tomb "at St. Benet's by Paule's Wharf" was adorned with surgical instruments and other appropriate devices. A further evidence of this interest is the explicit direction that these lectures were to be on surgery "for the common benefit of London and consequentlie of all England." It is stated that "before the foundation of these lectures there have been lectures on physic, though chiefly at the universities, that the needfulness of similar instruction in surgery is apparent, as hitherto hath been the want and lack so hurtful." It is also claimed that "the like thereof is not established nor used in any Universitie of Christendom (Bononie and Padua excepted), and therefore it is the more to be esteemed." It is recommended that they are to deal "onlie of surgerie and not of physicke." It further says "that part which onlie useth the hand, as it is sorted from the apothecarie." Caldwell also hoped that these lectures would be to the "common profit of Her Majestie's subjects and good fame, with increase and credit of all the surgians of this Realme." He was evidently both progressive and practical, for he directs that the lecturer shall "read for ¾ hour in Latine, and the other quarter in English, wherein shall be plainlie declared for those that understand not Latine, what was said in Latine." He was also "to dissect openly all the bodie of a man, especiallie the inward parts, for five days together, as well before as after dinner, if the body may so last without annoie."

The College evidently esteemed the gift highly, as it set aside £100, the major part of its reserve, to enlarge the College buildings, then consisting of the house devised to them by will of Dr. Linacre. It comes as a disappointment to learn that there is a note on July 17th, 1584, in the College records of the want of attendance at these chirurgical lectures.

This short incursion into historical matters is my apologia for my choice of subject. I feel that in presenting a Medical Review of the Surgery of the Chest, though I am departing from long-established precedent, I may yet conform in some small degree to the wishes of the pious and enlightened founders.

THE SURGERY OF THE CHEST.

Boundary or border areas are usually the scene of strife and conflict where countries or policies are concerned, and the subject of argument or polemics where ideas, ideals, or methods impinge on one another. The boundary zone of surgery and medicine is no exception. There is something fundamentally different in medicine and surgery. Medicine is in the main abstract, dealing with deranged organs and with disturbed functions. Surgery is in its essence concrete and mechanical, and is concerned in removal, adjustment, and adaptation.

There would be few to dispute that some of the greatest triumphs of surgery are in the failures of medicine, but, on the other hand, some of the greatest surgical tragedies occur where surgery has been ill-advisedly or unsuccessfully invoked in medical conditions. This is most emphatically true in regard to the surgery of the chest. If this branch of surgery is to advance, and I believe it to have a great and beneficent future before it, it must advance along right lines. There must be the closest, the most understanding and sympathetic coöperation between the physician and the surgeon. There must be a close conformity to the conditions existing between the neurologist and the specialist nerve surgeon, rather than to the conditions which unfortunately occur too often in regard to the surgery of the stomach and duodenum, in which some too enthusiastic surgeons have come to regard surgery as a primary means of treatment, which it is not.

Surgery can afford the most dramatic assistance to the physician in cases of disease of the lungs, bronchi, mediastinum, and pleura in cases otherwise grave or even hopeless. What is needed is a better understanding on the part of the physician and of the general practitioner of what surgery can do and perhaps even more of what it cannot yet achieve. Ill-informed opposition and too enthusiastic recommendation are alike to be avoided. In no branch of our science is efficient and adequately coördinated "team-work" more essential, but the physician should in the end be the predominant partner, or at any rate have the casting vote. The surgeon should be his co-adjutor and his agent, but certainly not his substitute. It is true that many surgeons who have specialised in thoracic surgery have been accomplished and skilled students of physical signs and of diagnosis. The late Sir Rickman Godlee was a first-rate observer, even with the stethoscope, as well as an accomplished surgeon, while I can testify that the present-day thoracic surgeon has often a knowledge of the medical aspects of thoracic disease which many physicians might envy. It is equally true to say a physician concerned with chest diseases should have a knowledge of surgical principles and technique at least sufficient to enable him to appraise the chances of success of the procedures he recommends.

This naturally raises the question whether in the future, if specialisation advances to its logical development, the diagnosis and treatment may not eventually be concentrated in one person. There is some precedent

for this, since Saugman, who helped on the progress of surgery as applied to pulmonary tuberculosis, did his own thoracoplasties. Brauer now carries out his own operations, and Gravesen, Saugman's successor at Vejlefjord Sanatorium, is both physician and surgeon to the patients under his care. I have an open mind on this subject, but I feel that at present the ideal arrangement is an understanding and critical coöperation between physician and expert surgeon. I like to discuss my cases with my surgical colleagues, and welcome criticism and alternative suggestions.

The team in regard to successful surgery in chest diseases involves more than the physician and the surgeon. The radiologist plays an increasingly important rôle, the bacteriologist, hæmatologist, physiologist, or biochemist may contribute crucial information, or even veto the appeal to surgery. Lastly, the anæsthetist is contributing greatly to the success of chest operations. The advances in his art have rendered the major operations possible and have eliminated many dangers. In this connexion it is not too much to say that the organisation of the surgeon's operative team is a most important factor in successful operation. The anæsthetist, the assistant, the sister and the nurses combine to form a coördinated mechanism which compels admiration, and which economises time and effort.

As I shall show later, time and the avoidance of shock are factors of vital importance to the patient. An operation like thoracoplasty demands great energy, concentration, and judgment, especially in regard to the extent of rib removal. In expert hands it is an admirable operation, in the hands of the tyro it is apt to be a shambles. It is for these reasons that it is to be hoped that, at any rate for the present, the more difficult and special operations will only be attempted by surgeons experienced in this work.

The early history of thoracic surgery in this country is in some senses a record of misfortune and of tragedy. The fundamental ideas and some of the earliest achievements stand to the credit of British observers. The essential and fundamental idea of collapse of the lung as the basis of treatment of many pulmonary conditions dates from Dr. Carson's [4] brilliant suggestions in 1820. He foresaw the benefit likely to result from collapse of the diseased lung induced by pneumothorax. In both cases in which he had attempts made to carry this out by open incision adhesions were present at the site and no pneumothorax was obtained.

Cayley,[5] in 1885, had an open pneumothorax induced by Pearce Gould to try to arrest severe hæmoptysis. Although the operation appears to have been effective in stopping the hæmorrhage, the patient died shortly afterwards from extension of the disease.

Cavities were drained as long ago as 1844 in this country by Dr. John Hastings and Mr. Storks.[6] Dr. Shingleton Smith injected medicaments into pulmonary cavities in 1885. Lowson [7] removed diseased portions of tuberculous lung in 1893, and Sir William Macewen [8] in 1895 removed the left lung for advanced tuberculous disease, probably with pyopneumothorax, the patient being alive 18 years afterwards. It was a misfortune that these successes were, as it were, accidental, and rather diverted attention from the more rational methods advocated by Carson, and now so fully established. Sir Rickman Godlee did most valuable work at the Brompton Hospital, and the thoracic surgery he carried out was sound and practical. The pioneer of the modern applications of chest surgery in this country is Mr. Morriston Davies,[9] who began to carry out special chest operations as early as February, 1913. His writings and his operative work are notable and stimulating contributions to the subject. His departure from London to a more restricted field of activity was a great misfortune, though he continues to do excellent special chest surgery in Wales.

The preoccupations of the years of the Great War doubtless further hindered the progress of chest surgery in this country, although owing to the coöperation of physicians, surgeons, and bacteriologists in the investigation of wounds of the chest, the treatment of these and of the conditions consequent upon them, such as hæmothorax and empyema, was stabilised and greatly improved. A further advance was the general recognition of the safety under ordinary precautions of thoracotomy. In these important developments, Sir John Rose Bradford, Prof. T. R. Elliott,[10] Dr. William Pasteur, Sir Wilmot Herringham, Dr. A. B. Soltau on the medical side, with Sir Berkeley Moynihan, Sir Henry M. W. Gray, and Prof. G. E. Gask on the surgical side, all played a notable part.

At the present time the rôle of surgery in chest disease is becoming more widely recognised and the special chest hospitals in London have developed arrangements to deal with the demand. At the Brompton Hospital a special surgical department, admirably equipped, is now in full working order in the charge of Mr. J. E. H. Roberts and Mr. A. Tudor Edwards. The results already obtained are more than encouraging. My colleagues and I find the assistance of our surgical colleagues increasingly necessary, as the indications for surgery become more clearly defined and the results more convincing. Similar work is being done at Victoria Park Chest Hospital by Mr. W. H. C. Romanis and Mr. R. H. O. B. Robinson.

The reasons why the surgery of the chest and especially that of the lung and mediastinum has developed later than other special applications of surgery are in the main: (1) The difficulty of access, owing to the bony thoracic cage with its serous lining. (2) The fear of open pneumothorax with the resulting collapse of the lung and sometimes rapid death. (3) The difficulty in collapsing cavities. (4) The risk of mediastinal flutter. (5) The occurrence of cerebral abscess and septic meningitis after empyema, bronchiectasis, and pulmonary abscess, first noted by Sir William Gull [11] in 1857. There is no reason to think that operation promotes these conditions, indeed we may hope that surgery will diminish their incidence. (6) The fear of gas embolism and of pleural shock or reflex. Both of these conditions are now rare with present-day methods.

Modern thoracic surgery dates from the last few years of the nineteenth century. Since that time its progress has been remarkable and the literature of the subject is now enormous. Modern developments in thoracic surgery have been rendered possible by: (1) A more accurate appreciation of the mechanics of respiration, including the intrapleural and intrapulmonary pressures, and of the part played by the mediastinum in thoracic physics. (2) Improved methods of diagnosis. (3) Modern developments in anæsthesia both local, regional, and general. (4) Rigorous selection of cases and careful preparation. (5) Improvements in technique, resulting in saving of time and avoidance or lessening of shock, with careful nursing, dressing, and after-treatment.

These factors may with advantage be considered categorically in some detail.

Respiratory Physics.

After the earliest inspirations of post-fœtal life the lungs are expanded, the alveoli become opened out by air, and the elastic tissue stretched, resulting after about four days in a constant tendency for the lungs to retract from the chest wall, which is expressed in a negative or subatmospheric pressure. The figures for these pressures, given by Donders, are those usually quoted—viz., −6 mm. of Hg at rest or in the cadaver, −7·5 mm. Hg at end of expiration, −9 mm. Hg at end of ordinary inspiration. At the end of deep inspiration it can reach −30 mm. Donders [12] is stated to be the first to have made these measurements in man in 1853, but Carson in 1820 recognised this elastic tension and its significance in regard to respiration and in promoting the circulation. Aron,[13] in 1902, made some actual measurements with a glycerine manometer on a normal,

healthy person, and obtained as a mean of 36 observations at the height of normal quiet inspiration −4·64 mm. Hg. and at the height of quiet expiration −3·02. At rest the intrapulmonary and intrabronchial pressure is naturally that of the atmosphere. It is 2 or 3 mm. Hg below this during quiet inspiration and an equal amount above it during ordinary expiration. In forced inspiration it may reach a negative pressure of −57 mm. Hg, and in forced expiration a positive pressure of 87 mm. Hg or even higher when breathing into and out of a closed space or against a mercury manometer. The pressure attained with forced expiration with closed glottis as in cough is therefore considerable.

It is important to remember in this connexion that the respiratory functions can be effectively carried out when the external pressure is below or above the ordinary atmospheric pressure, and this fact is utilised in some of the modern methods of administering anæsthetics. It must be borne in mind also that so long as the chest wall is intact the intrapleural pressure is always less than the intrapulmonary by just so much as corresponds to the degree of stretching of the lung tissue.

From the standpoint of thoracic medicine and surgery, the alterations induced in the pressure relations by gas and effusion in the pleural cavity, or by growths in the bronchi and mediastinum, are of fundamental importance. The history of our knowledge of pneumothorax up to 1903 has been exhaustively studied by Emerson.[14] Itard,[15] in his Paris thesis of 1803, first applied the convenient name of pneumothorax to the condition of gas in the pleural space, and he has often on this account been regarded as the discoverer of the condition. Emerson's historical survey has, however, established that Boerhaave, Meckel, and others had observed the presence of gas in the pleura. Hewson,[16] in 1767, clearly recognised the condition, and even suggested paracentesis thoracis to let air out of the chest. His teacher, Alexander Monro the younger, of Edinburgh, claimed priority for this idea, made in his lectures in 1761–62, and Hewson later admitted that he may have heard Monro make this suggestion. Hewson also observed that in gunshot wounds of the chest, the difficulty of breathing, which was often extreme when the wound was open, became greatly relieved when it was closed, an observation which the modern thoracic surgeon has often confirmed. It is interesting to note that in the fourteenth century Henri de Mondeville[17] advised the closure of penetrating chest wounds.

From the time of Itard pneumothorax became the subject of very numerous observations on the part of clinicians and pathologists. Laënnec was almost certainly the first to diagnose the condition during life, and with characteristic thoroughness gave an account of the signs, to which little has been added, save that he does not seem to have observed the displacement of the heart, which so commonly occurs. This was apparently first recorded by M. A. Gaide in 1828, though he states that Laënnec had seen it once.

Important contributions to the study of pneumothorax were made by our former President, Sir Richard Douglas Powell[18] in 1868 and 1869. He first pointed out that the heart and mediastinum are maintained in position by the balanced opposing negative pressures of the two pleural spaces, and that in pneumothorax the displacement is due to the unbalanced or unopposed traction by the sound side, and not to pressure; moreover, he was apparently the first to recognise that in valvular pneumothorax a definite positive pressure could occur, causing further displacement of the heart and mediastinum and increasing the embarrassment of respiration and circulation, sometimes to a dangerous or even fatal degree. His observations paved the way for the general adoption of the simplest form of thoracic decompression by insertion of a trocar into an intercostal space, and he recommended this to be done, although J. Davy in 1823[19] and James Johnson in 1829[20] had both demonstrated the valvular nature of the opening in cases of pneumothorax and both withdrawn gas by puncture, giving relief to the patients. This simple procedure often gives rapid and dramatic relief and has no doubt saved many lives. It is now generally performed by reversing a pneumothorax apparatus, so that the amount of gas withdrawn can be measured, and the pressures at the beginning recorded and those at the end of the operation controlled.

The classification of pneumothorax into open, closed, and valvular varieties appears to have been made first by Unverricht[21] in 1879, though Weil arrived at a similar classification in the same year on experimental grounds. This classification is still current and is useful.

In closed pneumothorax, whether the original opening be in the parietal or the visceral pleura, the gas quickly takes on the composition of alveolar air by diffusion, and is rapidly absorbed, unless the pleura becomes infected. It is for this reason that in therapeutic pneumothorax spaced refills become necessary. It is interesting in this connexion to note that as time goes on the pleura becomes less absorbent of the air, so that longer spacing is possible. In valvular pneumothorax the condition of the patient becomes rapidly grave, unless relief is given by paracentesis, as has just been described.

In open pneumothorax, when the opening is in the visceral pleura, the lung is collapsed and the intrapleural pressure on that side varies with the intrapulmonary, being practically atmospheric. The heart and mediastinum are displaced to the sound side unless prevented from moving by adhesions. In open pneumothorax with an external wound the conditions are less constant, and there is even at the present time some controversy both as to the actual facts and as to the explanations of the varying conditions observed. It is generally admitted that with a large unilateral external opening rapid and extensive, even complete, collapse of the lung occurs. Great distress and rapid death may result.

The explanation of the grave effects of widely open pneumothorax was supplied by Murphy in 1898.[22] He pointed out that with a free external opening into one pleura the lung in that pleura collapses during inspiration, but expands on expiration. The mediastinum and its contents are displaced by traction to the sound side during inspiration, with the result that adequate ventilation of that side is impeded. On expiration the mediastinal septum bulges towards the side of the open pleura and air is drawn into the collapsed lung. This to and fro movement of the mediastinal septum and its contents is now known as "mediastinal flutter." It is one of the conditions which has to be prevented in operations upon the thorax involving extensive removal of the chest wall, or wide opening of the pleura. Brauer suggested as a further cause of the increasing cyanosis and dyspnœa in these conditions that during expiration air from the sound lung was forced into the collapsed lung and during inspiration it was drawn back into the sound lung—becoming thus increasingly impure—a condition to which he gave the name of "pendulluft." Other factors in the bad effects of a widely open pneumothorax are the embarrassment of the heart, due to the flapping mediastinum, the disturbance of the pulmonary circulation induced by collapse of the lung, leading to a rise of systemic venous pressure as shown by Sauerbruch. The rapid loss of heat, also demonstrated by Sauerbruch, which is much greater than that caused by opening the abdominal cavity to an equivalent extent, is also a factor to be remembered.

It has long been known that these alarming effects of a suddenly developed open pneumothorax can easily be alleviated. Hewson as long ago as 1767 showed that blocking or closure of the opening rapidly lessened the dyspnœa. Sir William Macewen in his Cavendish lecture in 1906 advised turning the patient so that the opening of the pleura occupies the lowest position in the thorax. Closure of sucking thoracic wounds was early recommended in the surgery of the

recent war. Seizing the collapsed lung with forceps and bringing it towards the wound gives rapid relief. This is described in a dramatic account of a case of operation for sarcoma of the ribs by W. Müller [23] in 1893. An accidental hole was made in the pleura and the tumour sank into the pleural cavity. The lung at once collapsed and the patient appeared almost moribund. On pulling up the lung it filled with air and the grave symptoms disappeared. Other ways of preventing these symptoms are by the modern methods of anæsthesia with positive intratracheal pressure. Murphy showed in an interesting manner how little increase of pressure in the trachea was necessary to cause the collapsed lung to expand, and even to protrude through the opening in the chest wall, thus explaining why hernia of the lung instead of collapse can sometimes occur in chest wounds.

So far there is general agreement as to the effects of open pneumothorax. We can now consider some controversial matters. It is often stated that a small external opening can be made into the pleura without collapse occurring. To account for this a cohesive force analogous to capillarity was assumed and was strongly urged by Dr. Samuel West [24] on the basis of some experiments he made. Sir William Macewen accepted this explanation. More recent observations fail to substantiate this. Northrup,[25] in 1890, found experimentally in animals that collapse occurred even with a pinhole perforation. Emerson also brought forward experimental evidence against this cohesive force. Murphy, from the standpoint of the surgeon, stated in 1898 that he had never found the lung in contact even after a pinhole perforation. It is probable, therefore, that where collapse does not occur at once local or adjacent adhesions are the factors preventing the collapse. It is obvious that pleural adhesion, or thickening, rigidity, and adhesion of the mediastinal tissues must greatly influence the effects of external openings into the pleural space. The frequency of these adhesions in disease no doubt accounts for the fact that in the past, even before tracheal insufflation methods of anæsthesia, surgeons have been able to carry out extensive operations involving opening of the pleura, empyema operations especially.

Evarts A. Graham,[26] whose wide operative experience and carefully devised experiments invest his opinions with great weight, stresses the importance of regarding the mediastinum as a yielding rather than as a rigid partition, and therefore alteration of the intrapleural pressure relations on the opened side must produce changes on the opposite or normal side. In some animals, such as the dog, the mediastinal pleura is so thin that it frequently perforates when air is introduced into one pleura, and a double pneumothorax results. This has occasionally occurred in man. Duval [27] and Matas [28] at one time both suggested that there was a communication between the two pleural cavities in the dog—a view they have now abandoned. Even in man there are two relatively weak or unsupported areas in the mediastinal septum—viz., an upper one in front between the first to the third ribs, where the two pleuræ are in close apposition; the lower one is behind between the fifth and tenth dorsal vertebræ.

The former of these is of some importance since in cases of artificial pneumothorax treatment, unless the pressures used are carefully controlled, a bulge or hernia of the mediastinum may occur from the treated to the sound side. Brauer has recorded one case affecting the second of these weaker spots.

Graham maintains that in open pneumothorax the "vital capacity" plays a very important part. It is obvious that with an opening in the chest wall the open pleura and the sound lung compete for the air drawn in by the respiratory movements. If the pleural opening is so wide or the vital capacity so much reduced that the inspiratory input into the lung is below the normal tidal air requirements, death must result from asphyxia. Graham has worked out a mathematical equation by which, if the vital capacity is known, the size of the maximum pleural opening consistent with life can be calculated. Duval has criticised these views and does not associate the size of the opening with the risk of fatal asphyxia. He even advocates a large pleural incision, provided that measures are taken to ensure complete collapse of the lung. The discussion is rather of academic than of practical interest since the introduction of intratracheal methods of administering anæsthetics, but on the whole the balance of evidence seems in favour of Graham's views. The size of opening is also of special interest in regard to bilateral pneumothorax. That life was possible when both pleural cavities were opened by small punctures was demonstrated by Cruveilhier in 1836, and this has been repeatedly confirmed since.

The determination of "vital capacity" seems likely to become a matter of increasing importance in regard to operative procedures on the thoracic organs. The vital capacity is defined as the amount of air which can be expired by the deepest possible expiration after the deepest possible inspiration. The "tidal air" is usually from 500–600 c.cm., while the "vital capacity" varies from 4000–5000 c.cm. in male, 2500–4000 in woman, or more in people of large build or athletic habits. Many papers have been published on this subject, notably by Peabody and Wentworth,[29] Dreyer [30] and Yates.[31] There is a marked lowering of the vital capacity in various pleural conditions, in pulmonary tuberculosis, and in cardiac conditions.

Meltzer has pointed out the great, indeed almost prodigal, reserve afforded by Nature in regard to most vital organs. Life can be maintained by one-sixth, possibly by one-eleventh of the total lung area. The ratio of the normal vital capacity to the tidal air which may be regarded as the ultimate minimum of respiratory ventilation, is a striking example. Graham's contention is that in disease, if vital capacity becomes reduced to somewhere near the level of the tidal air, any further reduction becomes dangerous or fatal. He believes that some of the serious symptoms in therapeutic pneumothorax may be due to too much pressure reducing the vital capacity to a serious or fatal level. Determination of vital capacity may clearly be an important or even a crucial factor in negativing surgical treatment.

Improved Methods of Diagnosis.

It is a singular and an arresting fact that the incursions of surgery into the various departments of medicine have almost invariably resulted in improvements and even refinements in diagnosis, and not infrequently in advances in strictly medical forms of treatment. The surgeon demands as great accuracy as possible in topographical diagnosis, and he usually requires also an assessment of the degree of functional impairment of the diseased organ. At any rate, in regard to any vital or essential organ he needs to know if the mechanical measures he employs, whether removal, displacement or compression, will leave sufficient normally acting tissue to maintain life, with some reserve in case of special demands. Before calling in surgical aid, it is therefore the duty of the physician to investigate his cases in such a way that he may be able to answer as fully as possible the questions the surgeon may ask. It is true that the ultimate and final investigation may involve exploratory surgical procedures, but in the first instance the responsibility of initiating surgical treatment depends, and should always depend, upon the physician. The responsibility for the ultimate procedures adopted must, however, be shared by the surgeon as well as the physician.

Diseased conditions within the chest, especially in conditions deep at the base, at the roots, or in the mediastinum, may afford some of the most difficult problems in medical diagnosis. After the most careful study of the history, the symptoms and the physical signs, it not infrequently happens that only a tentative diagnosis can be arrived at, or a choice of several. It is fortunate therefore that the developments of laboratory and instrumental methods have yielded aid as great as, if indeed not greater than, in the

case of disease of other systems. It is necessary to emphasise, however, that as a matter of routine, the most careful study of the clinical features of the case should be made before the appeal to these special means of diagnosis, in order to obviate misinterpretation, because such methods by themselves may be as equivocal in their indications as clinical investigation alone. It is also desirable to spare the patient avoidable disturbance and unnecessary expense.

The chief special methods available are: (1) radiological; (2) bronchoscopic; (3) thoracoscopic; (4) clinical laboratory methods, including physical, chemical, histological, and bacteriological investigations.

Radiological Methods.

It would be difficult to exaggerate the value of the assistance given by X ray methods in the investigation of chest disease, particularly since the introduction of the method employing the tube at a distance of 4–6 feet to avoid distortion. Stereoscopic radiograms are also sometimes of great value in establishing the depth of the abnormal condition seen, and its position relative to other structures. For mediastinal conditions, oblique views may afford great assistance, while especially in regard to abscess, bronchiectasis and growth, a true or "dead" lateral view may give information of crucial diagnostic importance and be of more value than stereoscopic methods. The lordotic position is also helpful for bringing mediastinal interlobar effusions into view. It is not too much to say that artificial pneumothorax treatment should not be undertaken, except in emergency induction for hæmoptysis, unless full radiological investigation has been carried out, and unless the progress of treatment can be controlled by re-examination from time to time. Thoracoplasty without preliminary X ray examination is never justifiable in these days. Great as have been the gifts of radiology to the advancement of diagnosis and treatment in chest diseases, they have been notably increased by the use of lipiodol as employed by Sicard and Forestier [32] since 1922. Its special value is that it enables the bronchi to be mapped out with accuracy to their finest ramifications. Lipiodol is a special preparation of iodine and poppy-seed oil. It is not irritating, though it contains 40 per cent. of iodine, and as a rule it does not lead to the ordinary symptoms of iodism, except in persons hypersensitive to it, unless it reaches the alimentary tract. Every precaution should therefore be taken to avoid this mischance. Its use is now so general as to be almost a routine in cases of bronchiectasis and chronic abscess. Full details of the various methods of administration and of its use in diagnosis are given in the admirable little book recently published by Dr. F. G. Chandler and Dr. W. Burton Wood.[33] Amounts varying from 5–40 c.cm. are used, usually by injection through the crico-thyroid membrane or between two rings of the trachea. Ballon and Ballon, and Singer,[34] also give useful practical descriptions. The skin is first anæsthetised with novocaine, and the same substance is slowly injected into the trachea. Preliminary tests as to undue sensitiveness to novocaine and iodine should usually be made. The lipiodol, warmed to 100° F., is injected in a special syringe, after it is made certain that the nozzle of the needle is in the trachea and after the position of the patient has been adjusted so that the lipiodol can reach the side selected by gravity. Every effort should be made by the patient to avoid coughing before the films are taken, as the lipiodol may spread widely into the alveoli and the value of the resulting films be diminished or even vitiated. Incidentally such films, taken after cough, suggest clearly how in disease, infected material may be spread widely throughout the lung by cough. Other methods of introducing lipiodol are through the glottis with the aid of a laryngoscope, by injection through a bronchoscope, a catheter, or an intubation tube, and by an oral method described by Singer,[34] in which with the tongue held forward, lipiodol is injected over the base of the tongue and allowed to flow into the larynx. The indications, contra-indications, and dangers are clearly summarised by Chandler and Wood. From my own experience I have found it of the greatest value in confirming and establishing the diagnosis of bronchiectasis, in determining whether this condition is localised or bilateral, and in distinguishing between it and abscess, a matter of great difficulty in many cases. In abscess, lipiodol as a rule does not enter the cavity, because the lumen of the bronchus with which it communicates is usually obstructed by œdema or by granulation tissue. It demonstrates obstruction of bronchi by growth or pressure. It enables the bronchial tree to be demonstrated in some cases where an ordinary X ray gives little or no information owing to dense pleural thickening or widespread fibrosis. It can also be used to demonstrate the extent of pleural sinuses or fistulæ, although in cases of bronchial fistula it may not necessarily reach the pleura from the bronchial route. Although it usually demonstrates a cavity produced by tuberculous disease admirably, its use for this purpose is contra-indicated as a rule, especially if there be any activity of the disease. Other contra-indications are fever of any degree and marked iodine hypersensitiveness. Chandler and Wood rightly condemn its use in grossly septic conditions of the lung.

The X ray expert should usually be consulted in regard to the interpretation of the appearances yielded by his screen and film examinations, especially where he has a wide experience of chest examinations. His expert interpretation of the appearances, in the light of the clinical findings, which he should invariably be given, may be of the greatest assistance, whereas an interpretation of the X ray appearance alone may be misleading. In other words, his opinion may carry great weight in regard to the decision between alternative diagnoses. I have frequently to acknowledge with gratitude the assistance given me by radiologists in this matter. Time spent in consultation in the dark room, especially if the surgeon be also present, is usually time well spent.

Bronchoscopy.

Bronchoscopy has established itself as a valuable method of diagnosis and treatment in intrathoracic conditions, and its usefulness is not confined to diseased conditions of the trachea and bronchi. Its employment in regard to foreign bodies is now a commonplace, owing to the classical work of Chevalier Jackson. It would now appear that the thoracic surgeon must needs become an expert with the bronchoscope, or include a bronchoscopist in his team, since this instrument can give information of great importance in regard to abscess, bronchiectasis, bronchial obstruction from cicatrisation, pressure or growth, and in regard to tumours originating in the bronchi. To its use in treatment I shall refer later.

Thoracoscopy.

The introduction by Jacobaeus [35] in 1913 of the thoracoscope enabled the conditions within the pleura to be seen clearly after a preliminary artificial pneumothorax, notably such conditions as adhesions and pleural growths. It has also enabled the situation and relations of new growths of the lung and mediastinum to be studied, and it may be a useful preliminary to more active surgical measures of treatment in such cases. An improved form of the instrument has been described by Unverricht.[36]

Clinical Laboratory Methods.

These should be utilised fully. Sputum examinations should always be carried out and repeated with special precautions or special methods where necessary. Not only the tubercle bacillus and other pathogenic organisms, but also anaerobic saprophytes and organisms such as various spirochætes may be found and give indications for treatment. The possibility of streptotrichosis, blastomycosis, and other mould or fungus infection should be borne in mind in obscure

febrile destructive pulmonary diseases. Careful cytological and bacteriological examination of pus and other exudates as well as of the sputum may also give diagnostic information of value.

Biochemical methods may serve an ancillary function, notably in regard to calcium content, blood-sugar, blood-urea, and non-protein nitrogen estimations, which may be considered in assessing the suitability of a doubtful case. Blood counts, showing leucocytosis, may suggest pleural or pulmonary suppuration, or an eosinophilia may give valuable suggestions as to the presence of hydatid or other protozoal disease.

Complement-fixation tests may give information in regard to syphilis, tuberculosis, or hydatid disease. Another test which sometimes gives useful information, especially in regard to tuberculosis, is the "sedimentation rate" of the red corpuscles. It is of little value, if any, in diagnosis, but as a prognostic aid it seems likely to be of use. The value of the test is vitiated by the fact that the sedimentation rate is lowered in a variety of conditions other than tuberculosis. It has therefore at present only a relative value. At the same time, a persistently low rate is in my experience of grave significance, and a rising level as a result of treatment is an encouraging sign. It is markedly lowered in pleurisy and it shows a notable improvement in cases of artificial pneumothorax progressing favourably from the clinical standpoint.

Selection of Cases and Pre-operative Preparation.

The surgery of the chest should in nearly all cases be deliberate and unhurried. Emergency operations are exceptional and are practically confined to: (1) relief of tension in valvular pneumothorax; (2) partial aspiration of a large effusion causing dangerous pressure on the contralateral lung or leading to acute œdema of that lung; (3) immediate artificial pneumothorax in cases of grave and repeated hæmoptysis; (4) tracheotomy in bilateral abductor paralysis from pressure on both recurrent laryngeal nerves, a rare but well-recognised cause of urgent dyspnœa; (5) aspiration of a large and neglected empyema in a very gravely ill patient preparatory to operation by thoracotomy.

In nearly all other cases there is time for the most meticulous examination, and for all the necessary special investigations such as those mentioned in the previous section. The appeal to surgery should be made only after it is clear that medical measures are doomed to failure. On the other hand, in such cases the decision should be made as early as possible and certainly before the patient has become so debilitated that the risk of shock from operation outweighs the chances of success. Such delay is not fair either to the patient or the surgeon. On the other hand, the operative mortality from some of the more severe operations, particularly lobectomy, is considerable. The decision as to operation may therefore require a careful balance of the prognosis of the condition if untreated, with the immediate risks of operation, and the chances of ultimate success.

The mortality of these operations is steadily diminishing in expert hands, and is likely to do so progressively as surgical technique becomes more and more developed and the selection of cases becomes more eclectic. The preparation of the patient varies somewhat in the practice of individual surgeons. Most of them insist upon rest in bed under careful observation for from seven to ten days before such an operation as thoracoplasty or lobectomy. This often serves to establish relations of esteem and confidence between surgeon and patient, which may be of the utmost value. If there be any evidence of any catarrhal process such as coryza or bronchitis or any serious digestive upset, the operation is postponed. The condition of the mouth and nose is investigated, as any serious oronasal sepsis is a contra-indication. Purulent affections of the nasal sinuses naturally involve special risk. If there is marked anæmia a blood transfusion may be given. If the blood pressure is low—e.g., much under 120—attempts should be made to raise it, but a low pressure does not negative operation. Morriston Davies gives a course of tablets of suprarenal extract for ten days beforehand. Glucose is frequently given for a few days both by the mouth and with rectal saline injections. Alexander recommends digitalis if there is any cardiac weakness. Lilienthal suggests an investigation of the coagulation time beforehand, and if it is too long appropriate measures should be taken.

Before any operation for a condition with cavitation or dilated tubes, the utmost care is taken to promote expectoration before operation by expectorants and by "tipping" or change of posture. The strictest attention to details of this kind may make the difference between success and failure.

Developments in Anæsthesia.

The problem of anæsthesia in patients with disease of the chest has always been a difficult one, especially in regard to conditions like pulmonary tuberculosis, empyema, and any condition involving opening of the pleura. It is well recognised that in latent or quiescent tuberculosis general anæsthesia induced by chloroform or ether, or by mixtures of these substances, may be followed not infrequently by definite activity of the lung lesions, with more or less prolonged febrile exacerbations. For this reason it is advisable in operations on patients with pulmonary tuberculosis to employ local or regional anæsthesia when possible, and to use gas and oxygen rather than chloroform or ether for cases where general anæsthesia is essential. These facts account for the diversity of practice of chest surgeons in regard to the use of local or general anæsthesia.

There can be no doubt that the developments of local and regional anæsthesia have been of the greatest service in chest surgery, by lessening shock and post-operative pain and by enabling operations such as opening an empyema to be done with safety in patients seriously ill where a general anæsthetic would be dangerous, and this applies to children as well as to adults.

The fear of open pneumothorax led to the introduction of differential pressure methods of administering general anæsthetics. The first of these was introduced by Sauerbruch in 1904 at the instigation of Mikulicz. It was a small negative pressure chamber in which the surgeon and his assistants worked, the head of the patient being outside and his body inside, and the anæsthetic was given at atmospheric pressure. The pressure within the room was kept at 8 to 10 mm. Hg below the atmospheric pressure.

Positive pressure chambers were used, especially by Brauer, the conditions being reversed, the patient's body and the surgeon being in a room at atmospheric pressure, while the patient's head and the anæsthetist were in a small chamber at a slightly raised pressure. A similar result was obtained by various forms of mask.

These methods, though interesting historically, are now practically obsolete, since the striking researches of Meltzer and Auer in 1909. They showed that life could be maintained by the intratracheal administration of air in animals, even after all normal respiratory movements were abolished by curare, and after double open pneumothorax. It is interesting in this connexion to note that Vesalius in 1560 was aware that life could be maintained in this way and that it was again observed in 1667 by Robert Hook, who used bellows to supply the air. Elsberg,[37] in 1911, seems to have been the first to apply the intratracheal insufflation method of anæsthesia to the human subject. He was followed in this country by Kelly in 1912.[38] Cotton and Boothby,[39] in 1913, first showed that gas and oxygen could be administered in this manner, a demonstration which materially extended the possible applications of surgery to tuberculous patients.

There are now many ingenious forms of apparatus by which the anæsthetist is able to control the exact percentages of gas and oxygen, or of ether and air, supplied, and to vary the pressure at which the mixture is delivered into the trachea. He is thus able, at the

request of the surgeon, to deflate or inflate the lung on the opened side, while maintaining adequate ventilation of the sound lung and complete anæsthesia. It is often stated that gas and oxygen administration is followed by shock. This is not our experience at the Brompton Hospital, as it is administered by Dr. J. W. Magill.

The technique of anæsthesia, induced and maintained by an expert in these methods in a severe operation on the chest of a patient often weak and ill from prolonged disease, compels admiration in its orderly and almost perfect adaptation to the needs of the surgeon.

Improved Technique and After-care.

Time, the lessening of shock, and the prevention of too long exposure are factors of the utmost importance in thoracic surgery. Lilienthal [40] states that "rarely will a patient recover after an operation lasting more than 40 minutes of wide exposure." The ingenuity and attention devoted to the production of special instruments for removing the periosteum from the ribs and for their cutting are all striking, as are also time-saving details in the operative technique developed individually by surgeons in their practice. Equally important to the surgeon is the organisation of his team of assistants. Efficient, experienced, prompt, and purposive help are greatly saving of time. Mr. Morriston Davies tells me that he is so convinced that loss of heat is an important factor in shock that he keeps the operating theatre at a minimum temperature of 80° F. for thoracoplastic operations.

The after-care, especially in regard to the dressing applied and the degree of pressure exerted by it in cases of thoracoplasty, and the special nursing arrangements required by these patients, especially in regard to position in bed, cough, and expectoration, are all vitally important.

The Aims and Methods of Surgery in Diseases of the Chest.

Limitations imposed by time and my own lack of experience of the effects of surgery of the œsophagus, the heart, and the great vessels, compel me to restrict my review to the applications of surgery to diseases of the bronchi, lungs, pleuræ, and mediastinum.

We may now consider what help surgery can offer to the physician in the treatment of cases of chest disease. Almost before the dawn of the modern applications of surgery to this branch of medicine, Glück [41] wrote "ubi hæmorrhagia, ibi ligatura, ubi tumor, ibi extirpatio, ubi pus, ibi incisio," a pronouncement epigrammatic and terse, if hardly classical. Unfortunately his recommendations are, as we now know, often impracticable.

The chief ways in which surgery can aid in disease or damage of the structures in the chest are: (1) By securing rest to the part involved, particularly in disease of one lung. (2) By evacuating abnormal exudates, whether serous, purulent, hæmorrhagic, or chylous, at the right time and in the most effective manner. (3) By removing foreign bodies. (4) By collapsing cavities. (5) By excision or extirpation of growths or cysts of the bronchi, lungs, pleura, or mediastinum when practicable. (6) By the removal of diseased or damaged lung tissue which is beyond hope of repair, if it is sufficiently localised. (7) By decompression, where intrathoracic pressure relations are disturbed. (8) By exploratory thoracotomy to discover whether radical surgical measures are practicable in obscure lung conditions.

The chief measures designed to these ends may be enumerated: (1) Those designed to produce collapse or compression of diseased lung tissue: (*a*) Artificial or therapeutic pneumothorax. (*b*) Cutting adhesions where these prevent complete or effective collapse, a procedure sometimes dignified by the misleading name of "intrapleural pneumolysis." (*c*) Thoracoplasty, especially the posterior paravertical operation of Sauerbruch. (*d*) Extrapleural pneumolysis—packing by various tissues or extraneous substances to complete the compression of the lung where thoracoplasty alone is insufficient, more especially at the apex—then called apicolysis. (*e*) Phrenic paralysis, either temporary—phrenicotomy, or permanent—phrenic evulsion or exairesis.

(2) Evacuation of exudates is not always a matter of mere paracentesis or incision. The fear of open pneumothorax has given place to the more real anxiety to avoid widespread infection of the pleura. Some intrapulmonary collections are more safely evacuated through the bronchi by induced collapse, others by bronchoscopic washing out, and others by a two-stage thoracotomy and pleurotomy, the first stage to produce pleural adhesion, the second to incise the lung.

(3) Foreign bodies may be removed through the bronchoscope, or if this fails or is impracticable, by thoracotomy. The main bronchi can be reached by an extrapleural route, the divisions only by actual pneumotomy.

(4) New growths of the bronchi of simple character may be removed through the bronchoscope. Growths in the lung, if operable, usually involve removal of part of the lung—lobectomy. Growths in the mediastinum may be dealt with either by a transpleural route after a preliminary pneumothorax or by a direct thoracotomy involving removal of several pieces of rib. A trans-sternal route of approach is also often valuable.

(5) For the removal of diseased or damaged lung, the operation of lobectomy is theoretically the operation of choice, and this operation will be discussed in connexion with bronchiectasis and new growth.

(6) Measures to secure decompression or relief of increased thoracic pressure, either pleural or mediastinal: (*a*) withdrawal of air or fluid by paracentesis; (*b*) removal of ribs or cartilages as in Brauer's operation of cardiolysis for adherent pericardium. It is suggested that a similar procedure may in rare cases be helpful in cases of raised intrathoracic pressure from inoperable growths. Here, again, a trans-sternal or sternum-splitting operation may be helpful.

(7) Exploratory thoracoscopy as introduced by Jacobaeus is sometimes useful, but seems likely to be displaced by exploratory thoracotomy, which enables a more complete investigation to be made.

The principle of pulmonary collapse which is the basis of artificial pneumothorax treatment, and of some of the chief surgical procedures, is so fundamental that it is worth while to study briefly what effects it can produce.

In collapse by artificial pneumothorax the lung is allowed at first to retract away from the chest wall by its own elasticity, and later, if necessary, it can be compressed against the mediastinum by positive pressure. It thus becomes collapsed and airless, while cavities and dilated tubes are emptied. It has been shown by Bruns that the collapsed lung contains less blood and that the amount of blood circulating through it is diminished. As a necessary consequence the blood-flow through the uncollapsed lung is increased and a compensatory hypertrophy of the right ventricle develops. Graetz,[42] Shingu,[43] and others have shown that there is lymph stasis with dilatation of the lymph-vessels. Leroy Gardner [44] has demonstrated that this dilatation occurs at the periphery, with obliteration in the centre. If collapse is long maintained, a general increase of fibrous tissue may result, though this is not invariable. Caseous areas may be partly dried up and partly discharged by the bronchi, and not infrequently they become calcified. Cavities may disappear owing to falling in and coalescence of their walls. The pleura may be greatly thickened after prolonged collapse and fibrous bands may extend from it into the lung tissue. There is often marked fibrous thickening of the walls of the blood-vessels and bronchi. In spite of considerably advanced fibrosis, complete or partial expansion can occur when the treatment is terminated, even after several years'

collapse. At times, however, the lung fails to expand, and in such cases surgical aid may be required.

In thoracoplasty similar changes occur, though they are produced by allowing the chest wall to fall back upon the lung, more or less completely immobilising it but not obtaining such a complete collapse. On the other hand, it is a permanent deflation of the lung, and is maintained by the thickening of the pleura and by the new growth of bone from the periosteum stripped up from the sections of ribs removed.

It is important to note that both procedures may promote emptying of cavities, either pulmonary or bronchiectatic, though closure of the latter does not usually result. Indeed, after the use of lipiodol in bronchiectatic cases it is wise to allow time for this to be largely evacuated before collapse is induced, otherwise it may be pent up. It is significant in this connexion that in one of my cases of bronchiectasis at present at Frimley convalescing after thoracoplasty, the operation reduced the sputum from 20 ounces to 4 drachms in the day, yet when he was tightly strapped because of some pain he brought up 10 ounces of sputum within the next day.

The beneficial effects of these collapse forms of treatment comprise far more than the mere mechanical effects just described. Some immediate reactive changes often occur, especially after thoracoplasty, leading sometimes to febrile reaction and temporary loss of weight; this is soon followed in successful cases by a remarkable improvement in the general condition of the patient and by abatement and eventual disappearance of symptoms such as cough, fever, and night sweats. In other words, the toxæmic features become abolished. This is explained by the relative lymph stasis and by the cessation of movements of the lung, giving less opportunity for the absorption of the toxic products of bacterial activities. This in turn helps to improve the local condition, since the immunity processes are less swamped by these toxic products.

In my next lecture I propose to consider the applications of surgical methods to diseases of the lungs and bronchi.

OBSERVATIONS ON THE LOCALISATION OF INTRACRANIAL TUMOURS.

THE DISCLOSURE OF LOCALISING SIGNS FOLLOWING DECOMPRESSION OR VENTRICULOGRAPHY.

By HUGH CAIRNS, M.B., F.R.C.S. Eng.,

ASSISTANT SURGEON TO THE LONDON HOSPITAL; LATE ASSISTANT RESIDENT SURGEON, THE PETER BENT BRIGHAM HOSPITAL, BOSTON, U.S.A.

No one can have experience of intracranial surgery without perceiving how difficult it may be to localise an intracranial tumour, and how often operation is performed without the tumour being found. The object of this paper is to show that surgical intervention which falls short of removal of the tumour may so alter the signs and symptoms of the tumour as to enable a more accurate localisation of its position to be made. Changes of a similar nature sometimes occur in cases of tumour of the spinal cord after lumbar puncture has been performed. These are easy to interpret and may therefore be conveniently considered before the more complicated changes that attend surgical interference in cases of intracranial tumour.

The Effect of Lumbar Puncture in Spinal Cord Tumours.

It is well known that withdrawal of cerebro-spinal fluid by lumbar puncture may aggravate the signs and symptoms of a spinal cord tumour. The example may be quoted of an elderly lady who was carried into the Peter Bent Brigham Hospital suffering from paralysis of both legs. For the previous seven months she had complained of increasing weakness of the right leg, but she had been able to walk without assistance until one week before admission when, following a lumbar puncture, her legs became completely paralysed. At operation Dr. Cushing removed an intradural meningioma from alongside the mid-thoracic spinal cord and the patient made a complete recovery.

There is little doubt that in this case the withdrawal of cerebro-spinal fluid by lumbar puncture was directly responsible for the great increase of physical signs, thus converting an uncertain clinical picture into one of obvious spinal cord tumour. Presumably the withdrawal of spinal fluid so altered the position of the tumour as to produce a greater degree of pressure on the spinal cord, or on its blood-supply, with resulting loss of function.

It is thus seen that lumbar puncture, which might be termed a "minor injury" of the nervous system, is of value in diagnosis of tumours of the spinal cord, not only because it frequently reveals characteristic changes in the spinal fluid, but also because it may so aggravate the pre-existing signs and symptoms as to produce a clinical picture which is easily recognised as one pertaining to tumour. The changes which follow lumbar puncture may be much less prominent than those which occurred in the case of the old lady, and it is therefore important that after lumbar puncture in cases of suspected spinal cord tumour we should deliberately repeat the neurological examination in order to search for an extension of the physical signs. Increase in the signs may be taken as evidence of the presence of a tumour.

Observations of this nature have been made by numerous workers in the past, notably by Elsberg.[1] That analogous changes may be observed in cases of intracranial tumour does not seem to have been so generally recognised, yet it is clear from the examples presently to be described that such changes do occur and that they may become a vital factor in the successful conduct of any one case.

What forms of injury are likely to aggravate the signs and symptoms of an intracranial tumour? Withdrawal of cerebro-spinal fluid by lumbar puncture will often do so, but to such extent that it may produce sudden death, and for this reason lumbar puncture is held to be dangerous in all cases of suspected intracranial tumour that show signs of hydrocephalus. The mechanism of herniation of the cerebellar tonsils and medulla oblongata through the foramen magnum, which is responsible for the fatalities after lumbar puncture, is well known, and therefore need not be elaborated here. The surgical procedure which more commonly than all others is seen to aggravate the signs of intracranial tumour is an osteoplastic exploration that fails to disclose the tumour. This is known in neuro-surgical parlance as "the negative exploration."

The Negative Intracranial Exploration.

When we consider that an expert neurologist after most thorough clinical examination may be unable to make an accurate diagnosis of the situation of an intracranial tumour, and that many parts of the brain are difficult of access, it is, indeed, not surprising that intracranial tumours are often difficult to find at operation, the more so as only a limited portion of the surface of the brain can be exposed at a single exploratory operation, and the presence of a deep-seated tumour may be easily overlooked. The advent of ventriculography has provided us with an additional diagnostic weapon of great importance, yet this procedure is not so free from danger that it can ever supersede the exhaustive clinical investigations upon which we have hitherto based our efforts to localise intracranial tumours, and there are many cases of unlocalised tumour associated with great rise of intracranial pressure in which its use is definitely contraindicated. In such cases the method of ventricular estimation[2] may be used as an aid to diagnosis, but it not infrequently happens that a fairly confident opinion as to the situation of the tumour is formed on the history and physical signs alone, and the surgeon, without resorting to ventricular estimation, explores part of the brain by turning down an osteoplastic flap and fails to find the tumour. He may then seek to reduce the raised intracranial pressure by leaving a decompression, and in this way many patients with intracranial tumours are temporarily relieved of their symptoms even though the tumour has not been removed. Experience teaches, however, that certain patients become definitely worse. This change for the worse that may follow a negative exploration and decompression has in the past played havoc with the peace of mind of those who have attempted neurological surgery, and one operator of experience has confessed to me that whenever he had performed a craniotomy without discovering the tumour he dreaded to approach the bedside on the following day for fear of finding that his patient had become afflicted with hemiplegia, aphasia, or some other symptom that was not present before operation. While in the past this aggravation of symptoms after a negative exploration and decompression was frequently due to gross injury of the brain at the time of operation, or to the formation of a post-operative clot, we are now, thanks largely to the work of Prof. Harvey Cushing, possessed of an operative technique so delicate that injury of the brain at operation can be avoided by all those who have the patience to master and employ the appropriate methods. If we may assume that the brain has been treated with proper gentleness at operation, and that the field of operation has been left dry, it is almost certain that any new signs and symptoms that make their appearance after operation must be due to alteration in the position or size of the tumour, occasioned by release of pressure in one part of the intracranial chamber. This obvious inference and all that it implies does not appear to have received in the past the attention that it deserves. Its importance was impressed on me by several cases that I saw during a year's experience as assistant resident surgeon to Dr. Cushing, and particularly by the following case.

A Case Related.

The patient was a young woman, aged 20, admitted to the Peter Bent Brigham Hospital on Nov. 22nd, 1926.

Clinical History.—Her illness had begun nearly six years before with fleeting attacks of numbness of the right side of the body. These were followed by "fainting spells" and, within a year, by generalised convulsions. After each convulsion she would have violent headache, mostly occipital, and vomiting for two to three days.

For eight months she had noticed that she could not see to the right, and had experienced a feeling of eye-strain and occasional diplopia. In addition, there had been some unsteadiness in walking and difficulty in swallowing; also some loss of memory.

Examination showed bilateral papillœdema with considerable secondary optic atrophy. There were signs suggesting cerebellar disturbance—namely, nystagmus, generalised hypotonia and ataxia, and staggering gait. But investigation of the visual fields showed complete right homonymous hemianopsia. There was also diminished sensation to pin-prick on the right half of the body. Spontaneous speech was normal, but there was slight difficulty in naming objects. Her speech, however, was examined by several observers, and it was finally concluded that this questionable defect of speech was of no significance.

Diagnosis.—The main signs were right homonymous hemianopsia, signs of cerebellar disorder, and papillœdema. The diagnosis thus lay between tumour of the left temporal and left occipital lobes. Looking back it is difficult now to see how a mistake was made, but at the time the right-sided analgesia was disregarded, and it was considered that absence of muscular weakness and of definite aphasia favoured an occipital location. Occipital tumours and the cerebellar signs produced by them were being made the subject of special study at the time, and probably this weighed unduly in the decision to explore the occipital lobe.

First Operation (Nov. 26th, 1926).—Dr. Cushing reflected an osteoplastic flap to expose the left occipital lobe. The brain protruded and everywhere showed flattening of the convolutions, but there was no sign of tumour. The left lateral ventricle was tapped and appeared to be displaced medially. In closing it was necessary to sacrifice the bone of the flap. During convalescence the patient became obviously dysphasic and also showed marked weakness and spasticity of the right arm and leg, together with impairment of postural sensibility on the right side. These further signs, considered in conjunction with the right homonymous hemianopsia, left no doubt that the tumour was actually situated in the left temporal lobe.

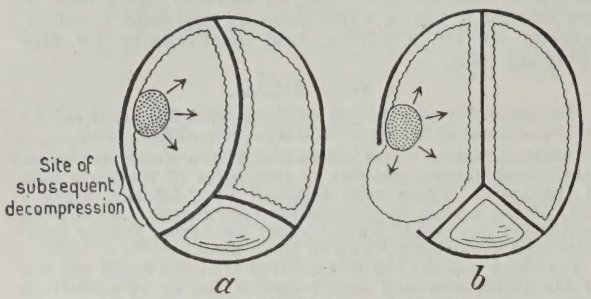
Second Operation (Jan. 6th, 1927).—Dr. Cushing turned down an osteoplastic flap over the middle portion of the left cerebral hemisphere, using the anterior limb of the former occipital exploration as the posterior limb of this new flap. In the cortex of the temporal lobe, and only 2 cm. in front of the area which had been explored at the previous operation, lay a large, soft avascular tumour. Tumour tissue to the size of a hen's egg was removed, mainly by suction. In closing it was again necessary to sacrifice the bone of the flap.

Subsequent Course.—After operation vision and speech improved, the headaches disappeared, and the attacks of unconsciousness became less frequent. On discharge from hospital, however, she still had some motor weakness and sensory loss over the right half of the body, also some difficulty in naming objects. The visual fields had not changed.

Comment on Case 1.

The importance of this case to our present thesis lies in the great increase of physical signs which followed exploration and decompression of the occipital region. A questionable difficulty in naming objects was converted into an obvious dysphasia. Paresis and disturbance of postural sensibility of the right side appeared as new signs. From our knowledge of localisation of cerebral function it is obvious that none of these signs could possibly have been due to local disturbance of the occipital lobe at or

after operation, and the reasonable inference was that they were attributable to a tumour of the left temporal lobe which, as a result of the occipital decompression, had become altered in size or in its relation to the left cerebral hemisphere. The change is represented diagrammatically in the figure. It is



In (*a*) is shown the probable state of affairs before operation. The presence of the tumour results in displacement of the falx cerebri to the opposite side. When the occipital decompression has been made (*b*), the occipital lobe bulges through the decompression. Owing to relief of pressure the falx tends to become straight. In addition the tumour is probably displaced backwards.

possible that withdrawal of fluid from the occipital horn of the left ventricle during the course of the first operation also played some part in the production of the fresh signs.

What happened in this case may occur in other cases where craniotomy has failed to disclose a tumour. After such an operation signs hitherto latent may declare themselves, and it is thus not infrequently possible to make a further and more accurate localisation of the tumour and to repair the original mistake in diagnosis by a second operation. Recognition of this principle has not been sufficiently stressed in the past, and doubtless in many cases its working has been overlooked because of a tendency to cease making neurological examinations once operation has been performed. In many cases the changes are so slight as only to be detected by thorough examination. In other cases the changes are more severe than in the case cited above. The fatal hyperthermia which is so liable to follow in the wake of simple decompression operations for tumours of the brain stem, such as pineal tumours,[3] and suprasellar cysts or adamantinomata,[4] is probably due to a shift in the position of the tumour in its relation to the vegetative centres of the hypothalamus. At present, however, too little is known of temperature control in man to render elaboration of this idea of any value.

It is clear that the possible effect of a shift of the tumour should always be considered when simple decompression operations are performed. When an osteoplastic exploration has been carried out and the tumour has not been found, there should be no relaxation of clinical observation. Almost at once neurological examination may reveal further signs which indicate unmistakably where the tumour lies, and the way will be open to retrieve the life and preserve the well-being of the patient by removal of the tumour at a second operation.

Ventricular Puncture and Ventriculography.

The following case is one of several in which fresh signs and symptoms appeared after replacement of the fluid of one lateral ventricle by air.

CASE 2.—A married woman, aged 45, was admitted to the hospital on April 4th, 1927.

Clinical History.—Her illness began 15 months before admission with loss of energy and initiative. Nine months before admission she began to suffer from headaches in the occiput and back of the neck. At this period her left leg began to drag while she walked, and at times it would give way and she would fall. After a vacation in August, 1926, she became very much better and remained perfectly well, except for an occasional slight headache until February, 1927, when, six weeks before admission, the headaches and weakness of the left leg returned. The leg was so weak that she was unable to stand. Her left hand also became weak, and in it she began to experience attacks of numbness which lasted five minutes. Her speech became slow, and she had difficulty in remembering the names of her friends. Her memory had been failing for about four months before admission. She was right-handed.

Examination.—The patient showed entire lack of anxiety about her condition, and was at times euphoric and subject to outburst of excessive laughing. Occasional incontinence of urine and fæces. Bilateral papilloedema. Slight weakness, slight ataxia and dysmetria of the left arm and leg. Inability to stand. Absence of left abdominal reflexes. Bilateral extensor plantar response.

The case thus appeared to be a fairly obvious tumour of the right frontal lobe, but some doubt was felt about this in view of the fact that sense of smell was impaired on the left side. Further examination also showed occasional weakness of the right side of the face. It was therefore decided to do ventriculography.

Ventriculography.—The left lateral ventricle was tapped through the posterior parietal region; 10 c.cm. of fluid were withdrawn and replaced by a similar amount of air. Thirty minutes after the air was injected, while the ventriculograms were being developed, the right arm was noticed to become extremely weak. There was also distinct weakness of the right side of the face and speech became slurred. The ventriculograms confirmed these recent clinical signs in showing a defect in the anterior horn of the left lateral ventricle.

Operation and Subsequent Course.—Accordingly on the day after ventriculography, the left frontal lobe, instead of the right frontal lobe, was explored. A tumour was found at the anterior pole of the left frontal lobe; over its surface was spread a delicate film of recent blood-clot. The tumour, a glioma, was almost completely removed, and the patient did well. Her mentality became normal, and she was able to walk quite well before her discharge from hospital about three weeks after operation.

Comment on Case 2.

This case affords a good illustration of the way in which a tumour of one frontal lobe may simulate a tumour of the opposite frontal lobe, but we are only concerned here with the alteration of physical signs that followed ventriculography and the manner in which it was produced. In this connexion it is important to note that a thin film of blood-clot was found on the surface of the tumour at operation. This clot was red, easily detached, and therefore evidently recent. There was, however, no reason to suppose that the clot was the result of hæmorrhage during the course of the operation, for there was no injury of the dura during the preparation and reflection of the osteoplastic flap, and the early stages of the operation were without incident. As soon as the flap was raised the clot was visible through the dura mater as a circular bluish-red area. In view of these observations it is probable that the clot was produced at the time of the ventriculography on the previous day. Withdrawal of fluid from the left lateral ventricle prior to the injection of air would tend to cause separation of the frontal lobe from the overlying dura mater, and may thus have resulted in rupture of some delicate vessel passing between dura mater and the surface of the tumour. It is always noticeable at operations that the anterior pole of the frontal lobe, more than any other part of the brain, tends to fall away from the overlying dura mater when the corresponding lateral ventricle is tapped.

Inasmuch as the air was injected into the left lateral ventricle by passage of a brain needle through the left parietal region, it is necessary to inquire whether the weakness of the right arm and face and the slurring of speech which followed within 30 minutes of ventriculography may not have been due to disturbance at the site of tapping in the left parietal lobe. There are no direct observations on this question, since neither the site of puncture nor the track of the brain needle was inspected at the subsequent operation. In a personal experience of ventriculography performed through the parietal

region, I have met with no other case that was followed by symptoms which could be referred to the site of brain puncture, but Dr. John Fulton tells me that he has seen a case in which symptoms occurred. In his case, however, the symptoms were not motor in character as in Case 2, but consisted of numbness and tingling in the opposite hand which came on at the very moment when the needle was being passed through the parietal lobe. In the case under discussion it seems more reasonable to attribute the symptoms that appeared after ventriculography to disturbance of the tumour itself. And the blood-clot which was found at operation on the surface of the tumour probably represents part at least of the disturbance.

The successful diagnosis and, depending so largely on the diagnosis, the successful outcome of this confusing case are to be attributed primarily to information furnished by the ventriculograms themselves, yet interpretation of these was difficult, and valuable evidence was obtained from neurological examination of the patient after the injection of air. Ventriculography intensified the clinical picture so that what had hitherto been nebulous in the light of current neurological knowledge now became clear.

The Misuse of Ventriculography.

It is scarcely necessary to point out that provocation of an intracranial tumour by ventriculography is not a thing to be desired or deliberately sought after. The degree to which the signs and symptoms may be aggravated by injection of air cannot be accurately predicted or controlled, and a certain number of fatalities will inevitably occur if air is used in cases that show a severe rise of intracranial pressure—that is to say, in cases which show a high degree of papillœdema, stupor, or intense headaches and vomiting. There are, however, a number of other cases where the rise of pressure is but slight or moderate, in which ventriculography is clearly indicated, because no exact localisation of the tumour can be made by clinical means, and the danger of failing vision precludes any delay. The fact that in such cases as these the symptoms may be aggravated or altered by injection of air is a clear indication that there should be as little delay as possible between ventriculography and removal of the tumour. The experience of Case 2 shows that the disturbance occasioned by ventriculography may take effect very quickly after the injection of air. Elsewhere [5] I have reported a case of hydatid cyst of the right occipital lobe in which, during the four days that followed ventriculography, the patient sank insidiously into a state of coma, from which he was only rescued by the most urgent measures. The literature now contains a number of records of cases of intracranial tumour in which the patient died a few days after ventriculography, though the relationship of injection of air to the aggravation of the patient's symptoms is not often commented on in the case reports.

Withdrawal of the air after the skiagrams have been taken will mitigate to some extent the danger of ventriculography, but too much stress cannot be laid on the fact that ventriculography should be followed with all possible speed by removal of the tumour at operation. The use of ventriculography by anyone who is not prepared to proceed, at once if necessary, with the surgical removal of the tumour is fraught with grave risks, and can only bring discredit to a method which, when properly used, is a valuable adjunct to clinical investigation.

Conclusion.

Evidence has thus been brought forward to show that the signs of intracranial tumours may alter after ventriculography and osteoplastic craniotomy and decompression. If these surgical procedures have been carried out with no error of technique the changes that occur in the clinical picture are to be attributed to change in position or size of the tumour itself. By recognition of this principle it is sometimes possible to make a successful diagnosis of the situation of a tumour that has already been sought for at operation without success. It is therefore advisable that a negative intracranial exploration should always be followed by careful neurological examination.

Observations have been reported that indicate the manner in which ventriculography may endanger life, even in those cases where its use is not contra-indicated by the clinical condition of the patient. To prevent loss of life in these cases it is urged that ventriculography should be followed at the earliest possible moment by removal of the tumour.

I desire to thank Dr. Harvey Cushing for permission to report these cases. It is scarcely necessary for me to point out that, while I must shoulder the responsibility for any conclusions that have been reached, the central idea of this paper arose from observing him at work in Case 1.

THE CHOLESTEROL METABOLISM DURING PREGNANCY.

By J. ADDYMAN GARDNER, M.A.,
READER IN PHYSIOLOGICAL CHEMISTRY, UNIVERSITY OF LONDON;
AND
HUGH GAINSBOROUGH, M.D. Camb., M.R.C.P. Lond.,
PHYSICIAN TO ST. GEORGE'S HOSPITAL.

At the present time our knowledge of the normal metabolism of cholesterol is limited, but extensive changes in it have been shown to occur in patients with certain diseases and have attracted increasing attention to this subject. We know that there is a great increase in the percentage of plasma cholesterol (both free and ester forms) in subacute parenchymatous nephritis, associated with an increase of the cholesterol ester content of the kidney. Hypercholesterolæmia has also been reported in pregnancy, diabetes, cholelithiasis, arterio-sclerosis, &c. Indeed, in order to explain the fact that 75 per cent. of cases of cholelithiasis occur in women, it has been suggested that hypercholesterolæmia occurring in repeated pregnancies is of paramount importance in the formation of gall-stones. The suggestion, however, does not help to explain the occurrence of gall-stones in men; also we have found in an examination of post-mortem records of this hospital that cholelithiasis had not occurred in cases of subacute parenchymatous nephritis, where hypercholesterolæmia rules much higher than in pregnancy. Some clinicians have even gone so far, on such scant evidence, as to eliminate from the diet of cases of cholelithiasis all substances rich in sterols, such as eggs, milk, butter, and other fatty foods, and have also suggested that the diet should be restricted in this way during pregnancy.[1]

Reports on the occurrence of hypercholesterolæmia must, however, be reviewed critically. Most observers use a definite figure such as 0·16 per cent., or other figure of similar order, as representing the cholesterol content of the blood, and any figure over this they regard as constituting hypercholesterolæmia. We [2] have shown that the normal cholesterol content of the plasma varies between wide limits, but that in a given individual in a state of health the plasma cholesterol tends to remain at a fairly constant level

for long periods. Hence in order definitely to establish a true hypercholesterolæmia it is necessary either that the cholesterol content of the plasma should be raised above the normal maximum limits or that, in the case of an individual whose normal plasma cholesterol content is known, the value should be definitely higher than in health. Bearing these results in mind we have thought it important to investigate the changes in the plasma cholesterol during pregnancy, especially as a "free" form, at any rate in normal subjects, whereas the plasma contains both forms. We have, in earlier papers, repeatedly stressed the importance of determining both the free and ester cholesterol rather than the total, because the distribution of cholesterol throughout the body suggests that the two forms have not the same significance in metabolism. In many of the papers mentioned only total cholesterol values have been recorded. Tyler and Underhill have

The Figures in the Table represent Weight of Cholesterol per 100 g. of Plasma.

Remarks.—CASE 3. Albuminuria. No nitrogen retention. Hydramnios. Some post-partum sepsis and pyrexia. CASE 8. Albuminuria. Slight œdema of legs. Fit during labour. CASE 9. Albuminuria, a trace. CASE 10. Normal pregnancy. Had eclampsia two years previously.

Patient's initials.—Case 1, E. C.; 2, M. L.; 3, M. B.; 4, B. G.; 5, A. O.; 6, I. W.; 7, A. S.; 8, F. L.; 9, O. V.; 10, D. W.; 11, W. B.

critical examination of previous work shows some of it to be vitiated by recognised fallacies.

Blood analyses during pregnancy have been reported by Chauffard and his collaborators,[3] by Herrmann and Neumann,[4] Klinkert,[5] Schimpert and Huffmann,[6] Mauriac and Strymbau,[7] Denis,[8], Bloor,[9] Slemons and Stander,[10] Pribram,[11] Kuster,[12] and by Tyler and Underhill,[13] with the general conclusion that hypercholesterolæmia occurs in pregnancy and the early puerperium.

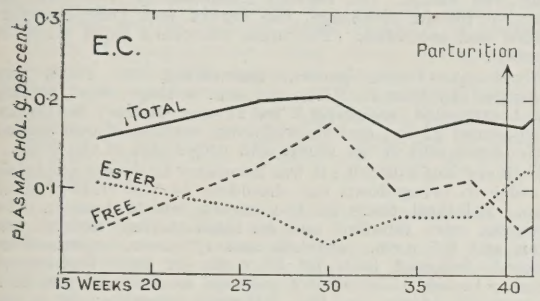
The Fallacy in Total Cholesterol Estimations.

The cholesterol throughout the body is present in two forms: as "free" cholesterol and also in combination with fatty acids, as esters. In the red blood cells practically all the cholesterol is present in the

presented a large amount of analytical data giving both free and ester values during pregnancy, but the cholesterol determinations were made on whole blood. This method must tend to mask certain changes, since the cholesterol of red corpuscles is mainly, if not entirely, in the "free" state and is fairly constant in amount, whereas the cholesterol of the plasma is present in both free and ester forms, the latter usually in preponderating quantity. Hence an analysis of whole blood, including the almost constant sterol content of red cells, tends to diminish the value of quite large changes in the plasma cholesterol. Another factor which may vitiate conclusions, drawn from analyses of whole blood, as to changes of cholesterol metabolism in pregnancy, is the phenomenon of the anæmia of pregnancy, which varies markedly in

different individuals and is often of considerable degree. There is, however, a more serious objection to Tyler and Underhill's results, which they acknowledge in their paper. Their method consisted in choosing ten women from each lunar month of pregnancy, and, with rare exceptions, different women were taken each month. The results of the analyses of the blood specimens were then averaged. This average figure, however, is an average of series of figures in which the variations from the mean are very considerable, as will be seen from a study of their tables. Mathematically, an average figure obtained from such a few cases,

CASE 1.

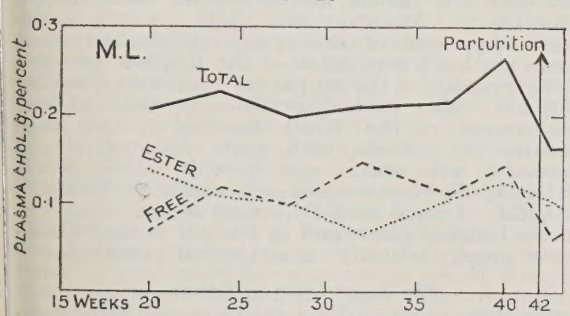


showing such wide variations, can have little value; just as in a study of the normal cholesterol content of plasma the significant values are the limits of variation and not the arithmetical average, which is less important. Finally, their results were obtained by colorimetric methods of analysis, which have been much criticised,[14 15 16 17] though in all probability the results of such methods are relatively correct.

The Present Investigation.

In our investigations we have examined a number of women attending the antenatal clinic at St. George's Hospital who were admitted to the lying-in ward for parturition. Owing to the hour of the clinic we were unable to take blood specimens in the "fasting" condition.[18] However, these women

CASE 2.

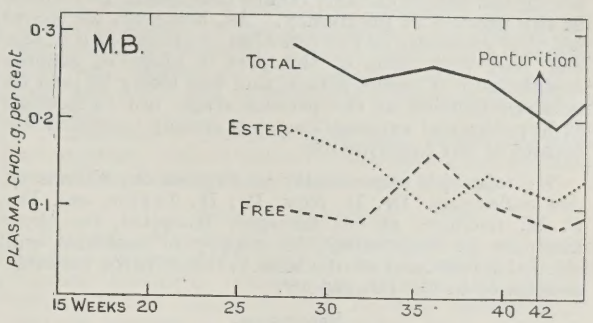


always attended at the same time of day, and, though it was practically impossible to control their previous feeding, this factor does not appear to have affected the results. Blood specimens were taken at monthly intervals before parturition and once or twice during the period of confinement. The analytical method used was that already described by us in detail [2] and, as 20 c.cm. of blood were required for each analysis, we were limited in our observations by the willingness of our subjects.

Our results are shown in the table; where a sufficient number of determinations were made the results are illustrated by graphs. The graphs are all characteristic, despite the fact that it was impossible, for obvious reasons, to obtain a sufficient number of blood samples to determine the exact shape of the curve. In the other cases in which still fewer observations were made, the results are in general agreement with the results from the more fully examined subjects.

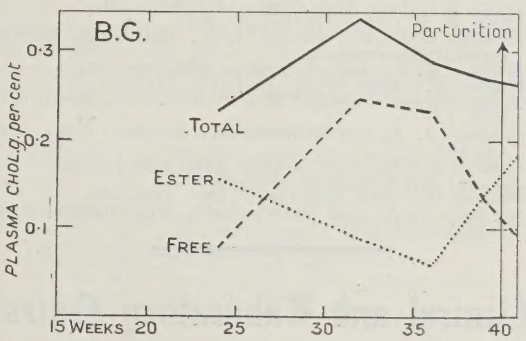
It will be seen that: (1) The free cholesterol of the plasma increases during pregnancy up to a maximum

CASE 3.



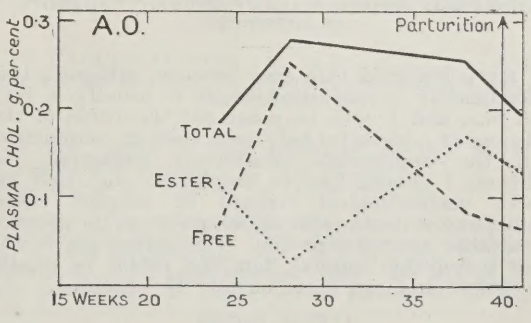
at about the thirtieth week; concurrently the ester cholesterol falls to a minimum at about the same time. (2) From the thirtieth week, more or less approximately, the amount of free cholesterol decreases and the ester cholesterol increases till an almost normal ratio of free to ester cholesterol is

CASE 4.



attained before or near parturition. (3) The plasma cholesterol values are generally normal in the first week or two of the puerperium. (4) Some cases show a definite total hypercholesterolæmia in which the total cholesterol figures run roughly parallel to the free cholesterol values. This is in general agreement with the results of the earlier observers, and our actual figures are of much the same order as theirs.

CASE 5.



During pregnancy there is a marked disturbance of the cholesterol metabolism which results in large changes in the ratio of free to ester cholesterol in the plasma, but to less definite changes in the total cholesterol.

We were tempted at first to correlate our results with changes that occur during the development of

the fœtus in the later months of pregnancy—for example, with the rapid growth of the brain and the accompanying marked tissue differentiation, since this organ is the richest of all organs in free cholesterol; or to suggest that the high free cholesterol in the mother's blood might serve the purpose of counteracting the effects of toxic bodies that might be formed in the process of pregnancy. As, however, we know nothing whatever of the function of cholesterol in the cell, and very little of the part it plays in general metabolism, it seems better, and less likely to lead to misapprehension at the present stage, not to indulge in hypothetical explanations, but simply to record the results of our experiments.

We take this opportunity to express our thanks to our colleagues, Dr. D. Roy, Dr. H. Taylor, and Dr. C. M. Gwillim, at St. George's Hospital, for their kindness in facilitating the supply of material and clinical details, and also to Miss A. Ratcliffe for valuable assistance in the laboratory.

Clinical and Laboratory Notes.

A CASE OF PUERPERAL INFECTION DUE TO *B. AEROGENES CAPSULATUS*, SUCCESSFULLY TREATED BY THE USE OF WEINBERG ANTIGAS-GANGRENE SERUM.*

BY FRANCES IVENS, C.B.E., M.S. LOND., CH.M. LIVERP.,
HON. SURGEON, LIVERPOOL MATERNITY HOSPITAL; CLINICAL LECTURER IN OBSTETRICS AND GYNÆCOLOGY, UNIVERSITY OF LIVERPOOL.

I HAVE reported this case because, although this is fortunately a rare infection, it is usually a very fatal one, and I wish to point out the value of the early use of a powerful antitoxin, used in conjunction with the appropriate obstetrical treatment. In addition, I should like to emphasise the need for expert bacteriological reports in suspect cases. Animal experiment is almost obligatory in the absence of suitable anaerobic media. The guinea-pig is the more susceptible animal, but the rabbit is locally susceptible and can more usually be obtained.

A Case Related.

A woman, aged 28, was admitted as an emergency case to the Liverpool Maternity Hospital on June 18th, 1928.

History.—The patient was a healthy primigravida of 28. Her last period started on August 15th, 1927, and she expected on May 22nd, but labour did not begin until nearly a month later—viz., June 4th, 1928. The patient was under the care of a midwife and had had no medical antenatal examination. When pains started on June 14th, the midwife ruptured the membranes, and as there was no advance a doctor was called in, who advised waiting. Nothing further was done until four days later, June 18th, when the doctor was again sent for, and at midday attempted forceps delivery ineffectually. Numerous vaginal examinations had been made by the midwife. The patient was sent into hospital at 2.30 P.M.

On admission the temperature was 98° F., and the pulse-rate 128. The external measurements were good except for the outlet, which was 3 in. in the transverse diameter. The abdomen was very large, the presentation a vertex position right occipito-anterior, but the head was above the brim and could not be pushed in. No fœtal heart was heard. On vaginal examination there was an offensive putrid discharge, the cervix was three-quarters dilated and lacerated. The urine showed a thick cloud of albumin.

Treatment.—Under general anæsthesia the vault was perforated by Miss R. Nicholson, and a large dead, peeling infant extracted, weighing 9 lb. 11 oz., without the brain. It measured 22 in., and showed large centres of ossification in the lower end of the femur and upper end of the tibia.

Delivery was difficult; it was necessary to divide a clavicle in order to bring down the shoulders as the child was so large. Bilateral tears in the cervix and a tear in the perinæum were repaired and an intra-uterine douche was given and 0·5 c.cm. pituitrin and 1·0 c.cm. ergotin were injected, followed later by 30 c.cm. of antistreptococcal serum. In addition, at my request, as there was such a gangrenous odour, on the following morning 20 c.cm. Weinberg antigangrene serum and 20 c.cm. anti-*coli* serum, also from the Pasteur Institute, were given subcutaneously with saline. From the profuse offensive lochia Prof. J. M. Beattie, by inoculation of a rabbit, isolated *Bacillus aerogenes capsulatus*, and the presence of *Bacillus coli* was also reported. After an early rise of temperature (temp. 99·8° F.) there was no pyrexia, but the pulse-rate remained high (130), and the cervix, vagina, and perinæum were œdematous and gangrenous. The patient had a yellowish toxic appearance, but no definite jaundice. Hypertonic saline packs in the vagina were employed, and she gradually improved and made an almost complete recovery at a convalescent hospital, though the uterus remained high and somewhat fixed.

The *Bacillus aerogenes capsulatus* (Fraenkel's gas bacillus), *B. perfringens*, or *B. welchii* is a large anaerobic Gram-positive organism which normally inhabits the adult intestinal tract. Although rare in the intestine of the breast-fed infant it is frequently found in those artificially fed, and more especially in infants suffering from gastro-enteritis. As a rule it is a saprophyte and does not invade deeper tissues until shortly before death. Weinberg and Nasta found it in the pus in 30 per cent. of cases of appendicitis, and recent researches have demonstrated the frequent presence of the organism in the subjects of pernicious anæmia.[1] Williams[2] also showed evidence of the immense proliferation of the Welch bacillus in the small intestine of patients with acute obstruction and peritonitis with stasis, and used *B. welchii* serum with good effect in a series of such cases at St. Thomas's Hospital. I have used *B. welchii* serum myself in similar isolated cases, and in Paris it is used extensively prophylactically in abdominal infections.

The Experience of Others.

B. welchii is especially fatal to women who have had criminal abortion induced, and numerous observations have been published in Australian literature. Beare and Cleland[3] recorded a fatal case of *B. welchii* infection originating in the uterus of a married woman aged 42 years, following an induced abortion. *B. welchii* was recovered after death from the uterus, liver, and heart blood.[3] Its presence in the blood is not always shown by clear clinical evidence. It may occasionally disappear after a few days without giving rise to a true septicæmia. In septic abortions Bingold made (1915–23) 120 positive blood cultures.[4]

When the bacillus has traversed the intestinal lining and is in the circulation it may localise and develop in the subcutaneous tissue at the site of a capillary hæmorrhage provoked by the injection of some medicament or subcutaneous saline. Weinberg and Francon (1919) have seen a case of gas-gangrene

* Read before the North of England Obstetrical and Gynæcological Society on Feb. 22nd, 1929.

of both thighs in a typhoid patient where spartein and adrenalin had been injected.

Toombs and Michelson[5] have collected and classified 41 cases of gas infection, including one reported by themselves, and consider that most cases follow abortion. The most marked symptoms are pain in the abdomen, rise of temperature, rapid pulse, jaundice, hæmaturia, and secondary anæmia, with expulsion of gas from vagina, physometra, or surgical emphysema. They consider hysterectomy, antitoxin, and blood transfusion to be the most logical methods of treatment. Recovery took place in 13·16 per cent. of these cases, and in the majority hysterectomy had been performed. The need for immediate operation was emphasised by the fact that 10 per cent. died within 24 hours and one-third in 48 hours.

Cases of gas-gangrene of the uterus are occasionally described under the name of physometra. In 1922 Brutt[6] described six cases of this condition following abortion, all treated by abdominal hysterectomy, with one recovery. Dobbin[7] reported a case of puerperal sepsis due to infection with *B. aerogenes capsulatus*.

A patient with a generally contracted pelvis had been in labour for several days under a midwife. On admission to hospital she was profoundly infected and the head of a macerated child was firmly engaged in the superior strait, and the uterus was in a state of tetanic contraction. A fœtid dark-coloured discharge was escaping from the vagina with a crackling sound. Delivery was effected by craniotomy, and death occurred the next day. Within a few hours the patient's body had nearly doubled in size as the result of gas development. The gas bacillus was found in the fœtus and placenta, as well as in the lochia.

Little,[8] in 1905, reported ten cases in the Johns Hopkins Hospital. In only one case did the bacillus occur in pure culture, but was often associated with the streptococcus. Welch[9] pointed out that the association of another organism seems to augment the virulence, and I can strongly corroborate that statement from my own experience of gas-gangrene in war wounds. He suggested that the gas bubbles found in the blood-vessels of women supposed to have died from air embolism are frequently the product of this bacillus. Gebhard,[10] in 1895, demonstrated the presence of *B. coli communis* in seven cases of tympanites uteri. It was shown by Henry[11] that the toxic power of *B. aerogenes capsulatus* is due partly to its hæmolytic action and partly to a substance which has a special affinity for muscle. When a woman after labour or abortion shows a yellowish tint and reddish urine it is probable that she is suffering from a severe *B. welchii* infection which is rapidly destroying the red blood cells. In these cases the hæmolytic nature of the jaundice is shown by the fact that the patients show no bilirubin in blood, cerebro-spinal fluid, or urine, nor yet traces of bile-salts. Recording two cases of gas infections of the uterus with jaundice due to *B. welchii* following abortion under the care of Magarey, Magarey, Cleland, and Sleeman[12] state that since the year 1920 a series of fatal cases has occurred in which jaundice was usually a prominent sign. The downward progress of the patients was usually rapid, death occurring two or three days from the onset of uterine bleeding. They consider the condition to be one of the commonest causes of loss of life following abortion in Adelaide Hospital patients. The patients all aborted at an early period of pregnancy from the second to the fifth month. Interference was suspected. It seemed that the most likely explanation of the gas-forming bacteria reaching the interior of the uterus was by the introduction of fæcal specks at the end of some implement used for bringing on abortion, as the vulval hair and orifice must frequently be contaminated with bacteria of fæcal origin. If these are once lodged in the uterus an excellent nidus is found for their development. They considered the most pronounced clinical feature in these infections to be the apparent lack of realisation by the patient herself of the severity of her illness. In contra-distinction to the anxious and worried faces of the ordinary general peritonitis patient, these patients are calm and unruffled. They seem to be mentally numbed, though quite clear and intelligent. This I know to be strikingly true in the classic form of gas-gangrene when, with the onset of septicæmia as the case progresses to a fatal conclusion, there is often a lemon-yellow coloration of the skin, an increase in the pulse-rate, sweating, coldness of the extremities, subnormal temperature, copious hæmorrhagic vomiting, and dyspnœa. The patient talks naturally, may eat well, and is generally conscious almost to the end.

Nürnberger[13] considers that local infection yields to curettage, but extension to the musculature requires immediate hysterectomy and serum therapy.

Rôle of Anaerobes.

The rôle of anaerobes in wound infection has been worked out very thoroughly by Weinberg at the Pasteur Institute. During the war he was able to isolate a new organism, the *Bacillus œdematiens*,[14] and to prepare a mixed powerful triple-antitoxic serum against *B. perfringens*, *Vibrion septique*, and *B. œdematiens*. His treatise,[15] gives an exhaustive survey of his work. The latest Pasteur antigangrene serum is a mixture of serums and contains in addition to the three previously mentioned organisms, one part of anti-*sporagenes*, to which organism is often due the fetid smell of gas-gangrene, and one of anti-*histolyticus*, which is believed to contribute to the intoxication of the body as a whole. To this serum has recently been added a powerful anti-coli serum.[16] To avert anaphylactic phenomena the serum is best given subcutaneously, at the time of operation, diluted with saline solution, and while the patient is under the influence of the anæsthetic.

AURICULAR FLUTTER AFTER DIPHTHERIA IN A CHILD.

BY PATRICK O'DONOVAN, M.D., M.R.C.P. LOND.,
RESIDENT MEDICAL OFFICER, NATIONAL HOSPITAL FOR DISEASES OF THE HEART.

A BOY, aged 5, was admitted to the National Hospital for Diseases of the Heart on Sept. 28th, 1928, under the care of Dr. John Parkinson.

History.—Five weeks before admission he seemed ill and complained of his throat. His mother saw some white spots on the side of the throat, but the doctor said it was not diphtheria, and a swab was not taken. He was, however, kept in bed for two weeks, but on getting up he was so pale and tired that his mother brought him to the out-patient clinic.

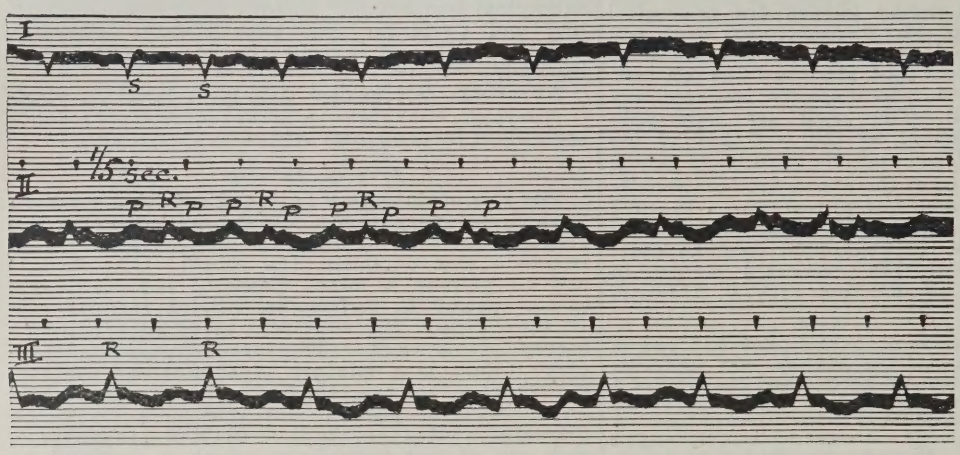
He was an only child, prematurely born (seven months), but of healthy parents. He always seemed frail and had scarlet fever, measles, and bronchitis, all within the previous year. There was no history of rheumatic fever or chorea.

Condition on Admission.—He was thin and strikingly pale. Weight, 33 lb.; height, 42 inches. The face seemed a little puffy, and this with a cloud of albumin in the urine gave a superficial resemblance to acute nephritis, but the

albuminuria cleared within a fortnight. There was no obvious dyspnœa, and no cyanosis, pulsation in the neck, or clubbing of the fingers. The heart rate was about 160 a minute on auscultation and irregular in rhythm—e.g., 30 regular beats, then a few irregular beats, then again 30 regular beats, and so on. The blood pressure was 105 mm. Hg systolic and 70 mm. diastolic. The apex-beat was in the fourth left interspace, just within the nipple line. No thrill was felt. On auscultation there was well-marked triple rhythm, apparently a duplicated first sound followed by the second sound. No murmurs were heard. The liver could be felt enlarged for about two inches below the right costal margin. The spleen was just palapble. There was no œdema and no ascites.

An orthodiagram showed enlargement of the heart (Fig. 4). An electrocardiogram taken on the day of admission showed auricular flutter with an auricular rate of 330 per minute and 2 : 1 block. In addition there was some left ventricular preponderance (Fig. 1).

FIG. 1.



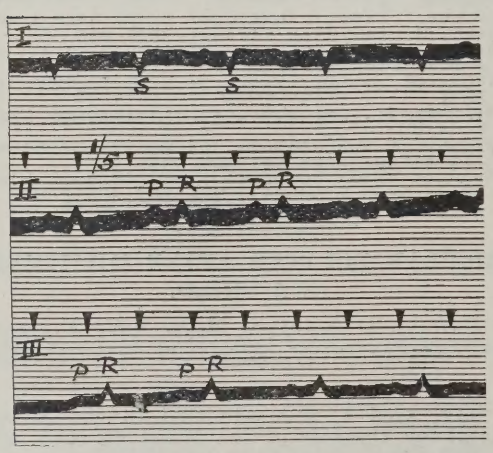
Electrocardiogram taken on admission, showing auricular flutter: A. 330, V. 165.

Course of Illness.—During the next few days in hospital the ward-sister noticed that he had a nasal voice. Examination of the nervous system then showed paralysis of both external recti muscles, so that lateral fixation produced squinting. The palate was paralysed, remaining immobile on phonation. The patellar and ankle tendon reflexes could not be elicited. The arm and abdominal reflexes were easily obtained and there was a double flexor plantar response. No sensory change was found. Nasal and tonsillar swabs proved negative for Klebs-Löffler bacilli. At the same time a Schick test gave a faintly positive reaction within 24 hours. The Wassermann reaction of the blood was negative. Some movement in the palate with complete recovery from the ocular palsy and return of the leg reflexes were noted in the sixth week in hospital—i.e., some 11 weeks after the so-called tonsillitis. The diagnosis of post-diphtheritic paralysis was thus confirmed.

On the third day in hospital, though the ventricular rate was still 160, an electrocardiogram showed normal rhythm (Fig. 2). During his subsequent stay in hospital repeated electrocardiograms never showed a return of auricular flutter. At the end of the first week his apex rate was 150, and triple rhythm persisted; the liver was smaller and the spleen no longer palpable. In the third week the rate had fallen to 120 and the liver was no longer palpable. Subsequently the heart rate fell to from 110–100, and remained at this level (Fig. 3). In the eighth week a modification of the first sound at the base merely suggested duplication. Twelve weeks after the disappearance of flutter he was up and about the ward, free from signs and apparently well. An orthodiagram now showed a heart of normal size (Fig. 4).

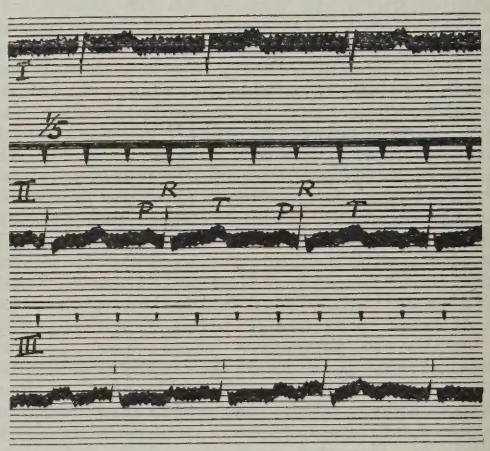
Dr. D. Evan Bedford has kindly furnished the following measurements from the original orthodiagrams. Fig. 4 (A): Oct. 8th, 1928, total transverse diameter (T.D.), 10·1 cm., area of frontal silhouette (area) 72 sq. cm., and cardiothoracic ratio 57 per cent. Fig. 4 (B): Jan. 4th, 1929, T.D., 7·9 cm., area 52 sq. cm., cardiothoracic ratio 47 per cent.

FIG. 2.



Electrocardiogram taken three days after admission, showing normal rhythm with simple tachycardia at a rate of 160 a minute.

FIG. 3.



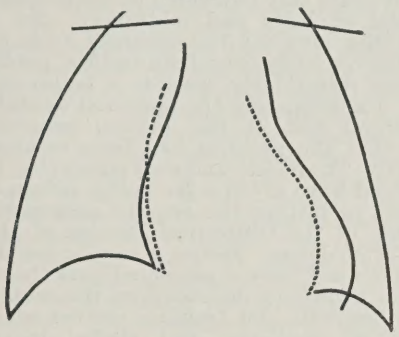
Electrocardiogram taken eight weeks after admission, showing normal rhythm at a lower rate (100).

Treatment.—The return to normal rhythm took place without the use of any drugs whatsoever, but he was kept strictly in bed for ten weeks.

Flutter in childhood, even apart from diphtheria, is rare. In the records at the National Hospital for Diseases of the Heart no case can be found in a child so young as here described. In the series of 50 cases of flutter published by Parkinson and Bedford [1] the youngest was aged 12. Poynton and Wyllie [2] have recently recorded a case of paroxysmal flutter in a

child observed from the age of 4 months to 3½ years, and whose electrocardiogram in an attack shows 1 : 1 flutter. Interesting and proved cases are also recorded by Lewis [3] and by Amberg and Willius,[4] the latter in a child with congenital heart disease. Speaking of the cardiac complications of diphtheria, Smith [5] says "of 242 patients (under his own care) the vast majority presented a rapid heart rate . . .

FIG. 4.



Orthodiagrams: (A) Continuous outline = on admission. (B) Interrupted line = 12 weeks after admission, showing smaller cardiac outline with recovery.

the initial tachycardia varied from 135–172." As other sequelæ he reports with electrocardiographic records, sinus arrhythmia, premature contractions, and heart-block. In his series there occurred neither paroxysmal tachycardia nor auricular flutter. Hume,[6] Bie and Schwensen,[7] and Schwensen,[8] report probable but not proved cases of flutter occurring after diphtheria. Smith [9] has published a unique case with a record taken at the moment of death in a child aged 4 with diphtheria, showing successively tachycardia, ventricular flutter, fibrillation, and heart-block.

Even paroxysmal tachycardia as a sequel of diphtheria is a rarity. Hume [6] reports a case with polygrams, and Marvin and Buckley [10] a case of ventricular paroxysmal tachycardia. Apart again from diphtheria interesting cases of unknown ætiology have been published by Koplik [11] and Hutchison and Parkinson [12] in children of an age ranging from 10 months to 10 years.

To summarise, a child of 5 years was seen five weeks after diphtheria with signs of heart failure. The electrocardiogram showed auricular flutter, which disappeared spontaneously within three days of admission. With the return of normal rhythm the same ventricular rate persisted for several days, and then fell quite gradually. Orthodiagrams showed a reduction in the size of the heart with recovery. No similar case of auricular flutter, confirmed by electrocardiogram, following diphtheria seems to have appeared in the literature.

My thanks are due to Dr. John Parkinson for permission to describe this case.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OBSTETRICS.

THIS Section held a joint meeting with the Maternity and Child Welfare Group of the Society of Medical Officers of Health on March 15th. The chair was taken by Dr. J. S. FAIRBAIRN, President of the Section, and Prof. J. MUNRO KERR opened a discussion on the

FUTURE OF THE MATERNITY SERVICES.

He pointed out that great advances had been made during the last decade in maternal and infant welfare. Antenatal supervision had definitely lessened the incidence and severity of obscure metabolic disturbances, and abnormalities in labour could be foreseen and thereby lessened in gravity. A large number of women became casualties because of faulty tactics in obstetrics, chiefly because of the difficulty of carrying out satisfactory tactics in domestic practice. Until quite recently the undergraduate had not received adequate practical instruction in midwifery, yet even the adequately trained undergraduate could not be regarded as a finished craftsman in obstetrics any more than in surgery. Nevertheless, the day after he was qualified he might be called upon to deal with a placenta prævia, though the public would never agree to his performing a major surgical operation. The trouble had arisen from the idea that parturition was an uncomplicated process, but often it was not, and in the simplest parturition there was a risk of sepsis. One grave abnormality alone—persistent occipito-posterior presentation—occurred in 20 per cent. of cases. The large body of practitioners did not want to engage in obstetric practice. Many had to undertake it because others did; they recognised it as a necessary evil which disorganised a crowded day's work. It was impossible for general practitioners in the middle of an influenza epidemic to give their obstetric cases proper attention. Their attitude was quite rational. All Prof. Kerr asked of the general practitioner was that he should allow those of his colleagues who were interested in obstetrics to modify domestic practice in such a way as to relieve him of the burden. The time was long past when the general practitioner could be a jack-of-all-trades. The future of domestic practice must lie in the direction of pure medicine, and the practitioner would only be enhanced in the eyes of the public thereby. The present high maternal and fœtal mortality and morbidity showed that domestic midwifery could not be satisfactory, and the reasons were: (1) the difficulty in securing surgical cleanliness; (2) the fact that midwives and nurses were expected to perform a number of domestic duties as well as attending to the patient; (3) the difficulty in securing adequate assistance if an operation became necessary; (4) the disturbance to the routine work of a busy practitioner, so that he was tempted to expedite delivery unnecessarily or prematurely; (5) the inadequate experience of practitioners in the craft of obstetrics now that 60–70 per cent. of the work had passed into the hands of midwives.

The Proposed Remedy.

Prof. Kerr suggested two forms of obstetric service, one mainly institutional and the other largely domestic. There should be, he thought, enough beds for all primiparæ, for all multiparæ whose labour was likely to be complicated, and for antenatal cases. The remaining normal multiparæ might be attended at home by midwives. A large number of patients might be transported to hospital by ambulance as soon as labour started and sent home again in the same way after three or four days. The fate of the parturient was sealed in the labour ward, and if all was well three or four days afterwards she could safely

go home. This was not suggested as ideal, but as an expedient to get over the difficulty of inadequate hospital accommodation. Obstetric beds should be concentrated in most carefully selected centres, which should be as few as possible, and should be in the hands of obstetric specialists. The alternative scheme would be to have a domestic obstetric service supplied by specialists, but it was very doubtful whether this would be as satisfactory. For a town like Glasgow and its environs about eight or ten obstetric specialists would be required. They would supervise the work of the midwives, which would serve to keep their work up to the standard inculcated during their training. Any scheme demanded the support of all branches of the profession and financial aid from the Government and local authorities. If, however, the doctors concerned did their part without bitterness the necessary money would be forthcoming. The public should realise that there would always be an irreducible minimum of casualties; puerperal infection could never be absolutely stamped out and there would always be minor accidents.

The General Practitioner's Part in the Scheme.

Dr. J. J. BUCHAN said that in his opinion the general practitioner was a very potent factor in public health—the outlying scout who saw early defects in health—and he would be very sorry to see him divorced from the same kind of work in midwifery. Child-bearing was a strictly physiological function and the danger involved should be very small. That it was not so was due to three things: (1) the number of women who were unfit for the ordeal of maternity because of defects in their health or development; (2) the want of knowledge or the failure to seek advice and help, especially early in pregnancy; (3) the want of facilities for advice and treatment. These were in order of importance; the first was by far the largest factor, and in the future an increasing amount of care and attention would be paid to the hygiene and development of girls. The cause of difficult maternity was in many cases to be found early in the life of the individual, and ought to be mitigated before any question of maternity arose. A certificate of fitness for marriage seemed to be involved, and it was certainly an important question how far the public might interfere to prevent the birth of diseased offspring. It was most important that the public, especially women, should know about the maternity service, and information should not be confined to the pregnant alone. Our insurance system had failed to appreciate the experience of Germany that benefits in kind were more helpful than benefits in cash. It would be of the greatest value if part at least of the maternity benefit could take the form of maternity service. The requirements of each locality must be considered separately. In industrial districts the midwife was perhaps the most important unit in the maternity service. She was a health officer; her duties were to observe and supervise normal conditions, and her duties to abnormal conditions ceased when she had recognised them and called in a medical attendant. Thereafter her duties as a nurse might begin in carrying out the doctor's instructions. She ought not to be at liberty to prescribe any drug or carry out any procedure for the correction of abnormality. Even the doctor should regard his duty as primarily hygienic, and only interfere if interference were unavoidable. Owing to the increased use of the midwife the doctor was apt only to be called in to abnormal cases, and to come to regard all midwifery as abnormal. Progress would be through development of the work of the midwife and the ordinary practitioner, not that of the specialist. In all public health activities it was the little common things that mattered, and these the midwife and general practitioner observed. Every pregnant woman, however, should be brought into touch, as early in pregnancy as possible, with the obstetric specialist—through the antenatal clinic, for instance—and the specialist must be a real part of the service, linking up all the others. Finally, without adequate hospital accommodation no service could be regarded as effective.

Mr. EARDLEY HOLLAND said that although institutional midwifery would be the midwifery of the future, we must in the meantime depend on the general practitioner and midwife. The standard of a maternity service depended essentially on a midwifery tradition, and in this country a great midwifery tradition did not exist. It must be inculcated in the medical public, whence it would spread to the general public. It could only be created by the proper training of medical students and midwives. Mr. Eardley Holland then reviewed the advances made since the war by the obstetric specialists and the public health authorities respectively towards a better midwifery service. Unfortunately the maternal mortality-rate, the essential test of the service, remained high, proving that the problem had been tackled in the wrong way. The money and man power that had been spent would have given a far better return if it had been used to further the reforms suggested by the committee of the Obstetrical Section of the Royal Society of Medicine. Before a service could become effective it must have a personnel, and the salvation of British midwifery depended on the establishment of large hospitals and training centres with a high standard of excellence, and staffed by obstetric specialists. These should have outposts staffed by junior specialists, and should serve a wide area by means of a good ambulance and telephone service. Every maternity hospital was dangerous unless it had three divisions: one for clean booked cases, a smaller one for emergency cases, any one of which was potentially a puerperal infection, and a still smaller division for frankly septic cases arising in hospital. A great deal of the puerperal infection arising in small maternity hospitals was due to mixing emergency cases with clean ones. The time would come when very few general practitioners would do midwifery. If these large centres were established they would provide a large number of young men highly trained in midwifery, and the public would learn to seek these practitioners for confinements. Any person who had charge of patients during pregnancy ought to be responsible for them during labour. The country had gone mad on antenatal work, and much of it was utterly irresponsible.

The Midwife and the "Handy-woman."

Dr. EUSTACE HILL did not agree that most general practitioners had no desire to practise midwifery. Many obstetric specialists were apt to take too narrow a view of the midwifery service problem and to forget the country district where, even with cars, it would be quite impossible to get a consultant to the patient until the need for his services had passed. Antenatal clinics were in their infancy and imperfect, but a proper antenatal service must be of great advantage to the community, and must provide the most expert obstetric opinion. He advised the following measures: (1) Improvement of the status of the midwife; the standard of education, the salary, the transport, and the holidays were all inadequate. The midwife should be a trained nurse with 12 months' special obstetric experience or else the period of training must be prolonged, perhaps by some system of post-certificate work under supervision. (2) Development of antenatal centres on the right lines. (3) Adequate bed provision in maternity hospitals or homes. (4) Adequate specific provision for sepsis. (5) Elimination of the untrained midwife or handy-woman. (6) Improved education of the medical student. (7) Alteration in the powers of the Central Midwives Board. The handy-woman was tacitly acknowledged by many doctors. It should be a sine qua non of maternity benefit that the woman should engage either a doctor or a qualified midwife, one of whom must undertake the confinement. It had been shown that a good maternity service of midwives could secure a maternal mortality-rate one-fifth that of the sparsely populated district where midwives were not available.

Discussion.

The PRESIDENT said that the great objection to domiciliary midwifery was the pressure brought to bear on the doctor by patient and relatives to end labour. The country was rapidly being urbanised, and it was therefore best to make a scheme first for the more populated areas.

Lady BARRETT suggested that certain measures might be taken at the moment to enable the general practitioner to do his work with greater facility and satisfaction. Every patient should employ a qualified midwife, even though she had a doctor as well, because it was quite impossible for the busy practitioner to give the time that the best midwifery required for letting things go on quietly under careful observation. The provision of a midwife for every case would soon do away with hurried midwifery and bring about coöperation. It might be possible for the midwife to give an anæsthetic in the later stages when the doctor was present. At the outside, the medical student had three months' training in midwifery, yet the young doctor was expected to go to the aid of a midwife who had spent 12 months training in midwifery. It was possible that we still had altogether too low a standard for the obstetric education of the doctor. The consultant service should also be extended to cover all difficulties in labour so that no doctor, however poor his patient, need hesitate to call in expert advice. All puerperal fever should be treated by obstetric specialists, and not in fever hospitals.

Dame LOUISE MCILROY brought forward the patient's point of view, and suggested that few women would care to be taken back to all the problems of their homes four days after their labour. She agreed that the future of the midwifery service lay very largely in the hands of the general practitioner, and that coöperation between doctor and midwife was very valuable. She was convinced that many deaths were due to the shock of the very painful process of labour without any sedative; were midwives, therefore, to be allowed to give sedatives and anæsthetics? She did not see how it was possible to have too much antenatal work. Where possible there should be a panel of general practitioners showing special interest or aptitude for midwifery to run antenatal clinics and follow up their cases. The Registrar-General's puerperal mortality figures ought to be analysed; they included, for instance, cases of pneumonia during the parturient period, although the woman's pelvic organs might have been perfectly normal. Antenatal cases ought not to be in the same ward with puerperal ones. A case of *Bacillus coli* infection would cause puerperal temperatures in that ward for several weeks afterwards. The obstetrician ought to treat all his own cases of sepsis; to teach students what sepsis was would teach them its prevention. Obstetric specialists were sometimes very unfair in their criticism of the general practitioner; they had done little to improve his position. Too often midwifery was taught by house surgeons or junior officers, while the chief only attended for occasional major operations.

Mr. W. S. A. GRIFFITH said that after 55 years' experience of midwifery he still held that the essential crux of the problem was the education of the doctor and midwife, and there was a crying need for its improvement. The cure for the "handy-woman" had been provided by the General Medical Council's notice about covering. At present only a small proportion of the trained midwives practised midwifery, because the prospects of reasonable pay and comfort were very small.

Dr. W. H. OXLEY said there was an enormous need for improvement in the training of students in practical midwifery, and it was marvellous how men learned in private practice to deal with the obstetric difficulties they encountered. The real obstetric specialists of the country were the general practitioners. It was a general practitioner who had taught in the middle of last century that diagnosis should be made abdominally and that vaginal examinations were undesirable. It was a general practitioner—the late Dr. Cursham Horner—who had inaugurated antenatal work on a large scale 15 years before Ballantyne. It was a general practitioner who had first drawn attention to the grave dangers of puerperal fever carried by droplet infection. Nothing whatever had been done by the obstetric specialists until the report of the Ministry of Health had alarmed the country. The amount of good work private practitioners did under vile conditions, and with no training, was surprising. He agreed with Dr. Hill's recommendations, but thought the only practical solution was an insurance maternity service, requiring a midwife for every case, a doctor for every emergency, subsidised hospital beds, and consultants for difficult cases. It would be wrong to provide a lot of hospital beds for normal cases. A halfpenny per week per insured person would supply all the funds necessary.

Dr. STELLA CHURCHILL said she would be sorry to see an extension of the National Health Insurance Act, as it would give more scope to the general practitioner without improving his training or results.

Sir EWEN MACLEAN said there was a tendency for people who did not know the difficulties of the obstetricians to bring railing accusations against them. Many midwives rendered excellent service, and anything that improved their training was all to the good. but in practice it was not always easy. In country districts the regulations of the Central Midwives Board were often disregarded, and there were still many handy-women prepared to attend a lying-in or a laying-out with equal zest. The ideal scheme was to have midwifery beds in direct association with the antenatal clinics of the local authority. The first and only practicable contribution to a maternity service was going to come from the further development of the insurance system. The general practitioner was the first line of defence, and his interests must be safeguarded if any scheme was to come to fruition.

The PRESIDENT recommended to those who depreciated the activities of obstetricians a perusal of the Transactions of the Obstetrical Society and of the Proceedings of that Section. Nearly all the recent enactments had been foreshadowed there.

Prof. MONRO KERR, in reply, remarked that the two greatest contributions ever made to the progress of practical medicine had been made by obstetricians—Semmelweiss and Simpson.

Dr. HILL, in reply, said that the difficulties of getting evidence against the handy-woman had proved insuperable in nine cases out of ten. No local pressure would eliminate her. The only way of arranging antenatal work in rural districts was for the general practitioner to do it; he was well able to undertake it, for the best men in the profession were the practitioners in scattered rural areas.

LIVERPOOL MEDICAL INSTITUTION.

AT a pathological meeting of this institution on Feb. 17th Dr. M. DATNOW read a paper on the

Effects of Lead on the Tissues.

After a brief historical review of lead poisoning he gave an account of experimental work carried out for the Liverpool Medical Research Organisation. The animal used was the rabbit, and the chief lead preparations used were the phosphate, aspartate, glutamate, hippurate, malate, iodobenzoate, and the benzoyl aspartate, in colloidal suspension containing 0·5 per cent. of lead. The lead colloid was introduced by intravenous injection. Dr. Datnow said that as the liver—with the possible exception of the spleen—was the main organ concerned in taking up lead from the blood stream, it was also the organ which first showed pathological changes. With massive doses or with very toxic preparations—e.g., 10 c.cm. of lead malate or 5 c.cm. of the more toxic benzoyl aspartate—extensive hæmorrhage was found throughout the liver substance. With therapeutic doses there was only transient cloudy swelling which

cleared up in 24 hours. This was confirmed by liver function tests and by clinical observations. Intermediate doses produced extreme dilatation of the capillaries with compression of the liver cells; the zone of the central vein was first affected. Similar changes were observed in the kidney. In the heart muscle apart from hæmorrhages with lethal doses no definite pathological changes were found. The spleen showed increased pigment with dilatation and congestion of the sinuses. Dr. Datnow also briefly mentioned the selective choriotropic effect of lead first pointed out by Blair Bell. He concluded by describing the effects of lead on rat tumours (Flexner rat carcinoma and sarcoma), demonstrating the destruction of the malignant cells with increased fibrosis in the tumours after treatment with lead aspartate.

HARVEIAN SOCIETY.

At a meeting of this Society on March 14th, held at the Paddington Town Hall, Dr. GRAHAM LITTLE, M.P. for the University of London, delivered the Harveian Lecture on

THE MEDICAL PROFESSION, THE VOLUNTARY HOSPITALS, AND THE DE-RATING BILL.

He said: This Bill, officially known as the Local Government Bill, is likely to bring the most drastic changes in our hospitals, in all the health services of the country, and in the actual exercise of the profession by the individual members of it. The Bill has two main purposes. First, the introduction of changes in the local government of this country, rendered necessary by the redistribution of the population and other causes in the century which has elapsed since the present system of poor-law administration was inaugurated—that is, 1834. The second purpose, the relief of rates, in a number of industries which are called "productive industries." The first purpose is obviously the more important, inasmuch as the Ministry of Health has been entrusted with the whole Bill, and it is this part of it that will be considered.

The Bill transfers the poor-law administration from the boards of guardians to the county councils and county boroughs, but the provisions of the Poor Law Act of 1927 are retained. It is a change of administration rather than a change of principle. The importance of the change to the medical profession lies chiefly in the power and even the encouragement given to the new county councils and county boroughs to provide hospitals and maternity homes, and the consequent probability of competition resulting between these new municipal hospitals and the voluntary hospitals already in existence has given rise to much uneasiness, very obvious in the debate in the House of Lords just concluded. Amendments proposed both in the House of Commons and in the House of Lords to provide some machinery for securing coöperation of the new municipal hospitals with the old voluntary hospitals, and so avoiding competition and overlapping, have been refused on the part of the Government, and it is true to say that at present there is no real check provided by the Bill to prevent that competition. The retention by the Minister of the complete control of all medical (and other) officers under this scheme makes a still wider extension of the medical autocracy of the Minister, already conferred by the National Health Insurance Act. About half of the entire medical profession in this country operates that Act at the present time. The medical staffs of the new municipal hospitals will also be under the control of the Ministry of Health. The Minister makes no secret of the desire of the Ministry, not as yet achieved, to extend the health services so as to include not merely the destitute but the sick, and thus foreshadows a nationalisation of the whole of the medical services in this country. A further extension of the power of the Ministry follows upon the changes in the relationship between the Exchequer and local bodies. The substitution of block grants for the percentage grants hitherto made to local bodies further increases the power of the Minister, for he reserves complete control of these grants, he may vary or modify them as he will.

The necessity, Dr. Graham Little continues, for providing further institutional treatment than the voluntary hospitals are able to supply in their present condition of development is conceded, but the means adopted for supplying this treatment may be questioned. The voluntary hospitals have been unable to meet the demands upon them because they have become so popular, and their funds have not allowed them to meet the demand as quickly as the public desire. The prestige of the voluntary hospitals explains why patients are willing to wait for admission to those institutions rather than to seek admission at the poor-law hospitals already in existence. There is no guarantee that patients will not still prefer to wait for admission at the voluntary hospitals. Government Departments cannot create prestige or personnel. A more logical and certainly a far more economical solution of adjusting the difficulty of empty beds at the poor-law hospitals and over-full beds at the voluntary hospitals would seem to be the provision of beds at those institutions where the demand is greatest. That provision could be made at a far smaller cost than would be entailed by starting new hospitals, and all the voluntary hospitals are, in point of fact, extending their accommodation as fast as funds will allow them to do so. Laboratories and special departments, which constitute so large an expense of hospitals, are already there, at the voluntary hospitals, and the consequent extra expenditure would be little more than the actual costs of providing new beds with a slight addition for the increase of the medical staff. The Ministry of Health, however, has determined upon the much more expensive and perhaps more dubious expedient of encouraging the establishment of quite new hospitals, and no provision whatever has been made to prevent competition with existing hospitals in each area.

During the last decade the voluntary hospitals throughout London and the country have become largely self-supporting institutions, and the voluntary system has developed into a great coöperative system of insurance, voluntary in character but growing rapidly to include quite new sections of the population. There is now an additional effort in progress to include certain sections of the middle classes. In these circumstances it is quite possible that the voluntary hospitals may elect to remain independent and to continue as they are now, outside the orbit of operation of the Ministry of Health, at any rate as regards their management. They would probably continue to attract, as they have in the past, the services, both lay and medical, of the best men and women of their time. Under modern conditions of medical practice the training of specialists who form the staffs of voluntary hospitals for the most part entails so many years of preparation that the supply is strictly limited. It would be quite impossible to staff the new municipal hospitals with officers of the same status as those who staff the voluntary hospitals without drawing upon the personnel of the voluntary hospitals. It is the freedom and elasticity of the voluntary system which has attracted such a high quality of service, both lay and medical. The importance of preserving this service seems paramount, but cannot be achieved without preserving freedom, especially freedom from departmental control. It would be entirely possible to blend the proposed new institutions with the old if a measure of freedom were retained. A central advisory body could be constituted to guide and coördinate health services throughout the country, this advisory body to be comprised of representatives of the County Councils, of the Ministry of Health, and the voluntary hospitals. In London the body representing the hospitals

might well be King Edward's Hospital Fund; in the provinces the body representing the hospitals is less obvious, but might be drawn from the Voluntary Hospitals Commission, or as Sir Arthur Stanley proposes in a recent letter to the *Times*, the Regional Committees of the British Hospitals Association. It is submitted that to keep the voluntary system intact in both lay and professional fields the representation of the voluntary hospitals must be predominant in this advisory council. The nearer the new hospitals approach to the atmosphere and practice of the voluntary hospitals the more probable is their ultimate success, in securing the confidence of patients, in maintaining economy and efficiency, and in winning the wholehearted and enthusiastic coöperation of the medical profession, upon which the success of any health scheme must ultimately rest.

Reviews and Notices of Books.

The Chemistry of Chemotherapy.

By G. Malcolm Dyson, Ph.D., Research Biochemist to the Laboratory of Applied Pathology and Preventive Medicine, Manchester. London: Ernest Benn, Ltd. 1928. Pp. 272. 32*s*. 6*d*.

This volume appears to be largely a summary of the well-known works on the subject, such as Fraenkel's "Die Arzneimittelsynthese." The writer sets about his task of writing the book in a somewhat patronising spirit. For instance, in the preface he says, "Details of symptoms have been omitted as far as is possible, and no references have been made to chemical details of synthesis and production, since this book is intended for the 'plain chemist' (if there be any such left!) rather than for the expert pharmacologist or for the 'compound maker.'" Quite early in the book Mr. Dyson expresses his opinion of the medical type of investigator; he says: "A third difficulty which could, possibly, be more easily removed, is the looseness of thought and even of experimental technique found widely among investigators in physiological, pathological, and pharmacological laboratories, leading often to generalisations based on insufficient evidence, often upon no real evidence at all. This has caused several especial difficulties which are met with in a critical survey of work done upon the subject of the action of drugs." This somewhat disdainful condemnation of his fellow-workers is not justified.

The first chapter of the book is entitled Physiological Action and the Nature of Matter. Here Mr. Dyson shows some lack of familiarity with physiological and pathological nomenclature. He was unfortunate, for example, in his choice of the term enzyme in the first paragraph, when he refers to the two classes of protective substances—first, the externally synthesised substances produced by the chemotherapeutist in the laboratory, "in contradistinction to the various substances *of the enzyme class* (our italics) which the animal is able to synthesise within itself as a defence organisation against bacterial invasion." On page 17 we get another reference to enzymes, where the author says: "The whole trend of the study of enzymes and their activities leads to the conclusion that their specificity—the 'lock and key' action of Fischer—rests finally upon the electronic nature of the molecular constitution, and that whilst their structural formulæ (in the conventional chemical sense) may reveal nothing concerning the reasons for their specific action, the energy relations of the ultimate particles which make up their molecules are the agents responsible for the development of specific activity." So much for the speculative and reflective part of the book. The sections on chemotherapeutics are clearly arranged, the substances being grouped according to their chemical constitution. Thus the compounds of carbon, oxygen, and hydrogen are dealt with in the second chapter; the third being devoted to the halogen derivatives. Chapters IV. to VIII. are wholly given up to the study of the simple and more complex compounds of nitrogen. The compounds of sulphur, selenium, and tellurium, and the organometallic compounds are respectively the subjects of the last two chapters. In each case the structural formula is given, together with a few details of the chemical properties of the substance in question and a summary of the pharmacological action, the minimum lethal dose of practically all the compounds being included. The author deserves praise for his method of expressing the minimum lethal dose. In one formula he gives the animal used, the amount of the drug per kg. used, and the method of administration. It is to be hoped that other writers will follow this pattern of expression.

The place of the volume in the literature is not easy to assess. It does not contain enough information to make it complete in itself, whilst it is really too big to be used merely as a text-book. It shows evidence of much hard work. The information collected is accurate and a really good bibliography is appended.

Common Colds.

Cause and Preventive Measures. By Leonard Hill, M.B., F.R.S., Hon. A.R.I.B.A.; and Mark Clement. London: William Heinemann, Ltd. 1929. Pp. 126. 6*s*.

"To inform a patient" say the authors of this little work "that he is suffering from a 'catarrhal cold' is to tell him what Hippocrates might have told him 400 years B.C. . . . Such a diagnosis has some historical importance, but it has little scientific value." It is the word "cold" to which the authors particularly object, and the experiences of Nansen, the Tierra del Fuegeans, balloonists, and Dr. Chodounsky, who stood naked before his window at 0° C. for 55 minutes, and not only failed to catch cold, but cured his rheumatism, are quoted in proof of the international fallacy of talking about catching cold.

Ventilation, an open-air life, and good food are stated to be the great enemies of the cold. The kiss has a small section; "If a kiss has to be given, let it be on the forehead, or the neck." The pollution of the air by smoke, the perambulation of the infected, the abuse of alcohol and tobacco, are all included in the ætiological retinue of the common cold. In fact, to use a rather homely but appropriate phrase, it would seem to be a whole-time job to avoid catching a cold—a sentiment with which the reader's experience will concur.

A vast amount of somewhat ill-arranged information about colds is assembled in this book, but it fails to obscure the sad fact that we do not know what a cold is or how to cure it. The bacteriology of the cold is the bacteriology of the normal respiratory tract thrown out of proportion. The transmission of colds by filtered exudates from the throat of a patient would seem to suggest a filter-passing virus save that we do not know what such viruses are, and the suspicion that bacteria may have filterable phases in their life-history is shared by a number of workers. Vaccine prophylaxis is fully considered. Results are proverbially variable and often disappointing. In a closed or partly closed community, a vaccine prepared from representative and parochial colds is often efficient. But the average man, whose embraces are not always on forehead or neck, and whose places of business and methods of transit fall far short of the spartan conditions enjoyed by Dr. Chodounsky, must needs encounter bacterial enormities which the most polyvalent vaccine has not foreseen. The polyvalent vaccine is, in fact, the prophylaxis of Goliath; there is always a joint in the armour. And it is possible to argue that vaccines protect not against colds, but against their sequelæ.

It is a little disappointing to find that one of the shortest chapters in the book is that on treatment,

and that the reader will probably find his favourite cure relegated to "old-fashioned methods." But the authors, of course, are chiefly concerned with preventing colds. And, if the reader will conscientiously carry out all the advice here given on preventing colds, he will be far too busy to notice his cold when he contracts it.

HOSPITALS AND THE STATE.

A Popular Study of the Principles and Practice of Charity. By R. WESTLAND CHALMERS, M.B. London: John Bale, Sons and Danielsson. 1929. Pp. 143. 6*s*.

Dr. Westland Chalmers surveys private philanthropy and the growth of a public conscience in hospital matters in England, with due note of well-known landmarks such as the Black Death, the suppression of the monasteries, the Elizabethan poor relief statute, Dickens's novels, and the National Insurance Act of 1911. He gives full credit to the voluntary hospitals, but he finds voluntaryism precariously kept alive by an intensively stimulated charity, attacked by many difficulties of which the main root is finance, and unequal to the task of the extension of institutional agencies necessary for the prompt detection and cure of disease. Only the State, he believes, can perform this task by extending statutory hospitals of a specialist character; the present overlapping and competitive methods, he thinks, must give way to a systematic policy on the lines proposed by the 1920 Coördination Scheme of the Medical Consultative Council, otherwise known as the Dawson Report. Lord Dawson's more recent observations (on the second reading of the Local Government Bill) regarding the "official doctor" are a further warning. The book is written vigorously but with occasional lapses as when the Great Fire of London is said to have "decimated" 436 acres within the City walls. Compiled just too soon to address itself to the concrete proposals of the new local government legislation, it is nevertheless timely in its estimate of the future of State intervention based on past history.

MEDICAL ADVENTURE.

By ERNEST WARD, M.D., F.R.C.S. London: John Bale, Sons and Danielsson, Ltd. 1929. Pp. 291. 8*s*. 6*d*.

MEDICAL adventure is the well-chosen title of a remarkable book. It is a record, freely annotated, of a man with a rich experience of many sides of a doctor's life. The author has served his apprenticeship as a general practitioner, as an expert witness in medico-legal cases, and as a unit in the administration of the tuberculosis service. In each of these spheres he has shown a chameleon-like fidelity in adjusting himself to his surroundings; as a general practitioner he has had "close-up" glimpses of humanity at its best and worst; as an expert witness he has revelled in those gladiatorial joys and spectacles which the law-courts offer every day free of charge (to the spectator); and as an administrator he has acquired that atmosphere with which even those of us who are left without the pale are so intimately and sometimes painfully familiar. The author is quite at his best in the first parts of his book. Here he gives us one anecdote after another, flavoured with caustic humour, illuminating the pitfalls awaiting the unwary practitioner. Many of his anecdotes illustrate problems in obstetrics and should prove most useful as well as entertaining to young practitioners. This is not the place in which to steal much of Dr. Ward's thunder, but it may perhaps be permitted to quote him on the prolonged disability which may follow even uncomplicated fractures of the ankle. "The editor of a leading medical journal once told me that he fractured his ankle 30, or it might be 40, years ago and that it still felt 'like a testicle.' A little tender, I gathered, when he trod firmly upon it." One of the many useful lessons the author teaches as a former expert witness is the wisdom of being modest. He has both the courage and the modesty to tell stories against himself in the witness-box. In this critical age few are impressed, while many are irritated, by the medical expert who poses in the witness-box with a magisterial air and with the expression of an omniscient divinity. Were it not for the wealth of technical detail in this book, it would make excellent reading for the layman as well as for the doctor. Perhaps the author will one day bring out an edition adapted for this purpose. It should have a great success.

GENERAL MEDICINE.

Ergebnisse der Gesamten Medizin. By numerous contributors. Under the general editorship of Prof. BRUGSCH, Director of the Medical Clinic of the University of Halle. Berlin: Urban and Schwarzenberg. Vol. XII. Part II. 1928. Pp. 340. M.35.

THIS volume is the most recent of the series of the large modern publications under the above title. There are eight original articles in it on clinical and scientific medicine. The subject of the heart and circulation during sport and gymnastics is continued from Volume X. A really important contribution on radiotherapy in disorders of the thyroid gland includes biological considerations, the particular technique of the treatment of Graves's disease with radium and X rays, the therapeutic measures available in the rarer thyroid maladies, and a complete modern bibliography. The early diagnosis of phthisis by radiology is another subject dealt with exhaustively and illustrated by many good reproductions of skiagrams. Perhaps the most important article of the eight is the one on the pathology of rickets. This contains a review of the status of the disease in the light of modern vitamin research with particular reference to the place of activation of the pro-vitamins and the isolation of vitamin D. The subject matter is fortified with tables showing the broad relationships between latitude, sunshine, climate, season, and rickets. The chemical and nutritional aspects of rickets are fully summarised with a review of the experimental production of the disease. But the author's main concern is with the activation of the pro-vitamins and the identity of vitamin D. There is nothing new in a lengthy article on Hodgkin's disease but it is well amplified by charts and photographs. Other articles include one on primary glaucoma with special reference to treatment, another on bile-pigments and the chemistry of icterus, and another on the biological aspects of colloid chemistry.

DISEASES OF INFANTS AND CHILDREN.

Sixth edition. By H. D. CHAPIN, M.D., Emeritus Professor of Diseases of Children, New York Post-Graduate Hospital; and L. T. ROYSTER, M.D., Professor of Pediatrics, University of Virginia. London: Baillière, Tindall and Cox. 1928. Pp. 675. 30*s*.

TWENTY years have elapsed since the publication of this book in its original form by Prof. Chapin and the late Dr. Pisek, and the appearance of six editions in this period bears witness to its continued popularity. The new volume is slightly larger than its predecessors; it contains numerous minor additions, while the authors' original intention of describing diseases in a condensed form has been adhered to. The distribution of space is somewhat uneven, feeding and diseases of infants being treated in much greater detail than are the disorders of childhood. An interesting feature is the authors' account of the treatment of epilepsy by ketogenic diet, by means of which they have obtained results which are distinctly encouraging.

The volume is well and fully illustrated, and is likely to prove as popular as the earlier editions.

THE LANCET.

LONDON: SATURDAY, MARCH 23, 1929.

SUN-WORSHIP.

TEN years ago it would have seemed as incredible that a simple article of diet would be found to cure pernicious anæmia, as that the controversy, then acute, centring round the causation of rickets, would be settled with honours easy. The first discovery has as yet no theoretical significance; it is an isolated piece of knowledge of immediate practical value. Of far greater import is the merger of the two contradictory conclusions about the ætiology of rickets. These conclusions were founded mainly on clinical observations, fiercely upheld, that rickets could be prevented and cured respectively by (1) the administration of cod-liver oil, (2) exposure to fresh air and sunlight. The curious explanation—namely, that the avitaminosis of which rickets is the manifestation is subject to dual control, forms a warning that widespread clinical impressions, even if they seem to conflict with one another, cannot safely be neglected. We summarise in another column the comments of the Medical Research Council on artificial light among the other therapeutic innovations reviewed in their report for 1927–28. It is good that the physiological bases so far established for such treatment should be clearly defined and that our deficient knowledge of the way in which light acts should not be masked by jargon. But the scepticism implicit in the report as to any effect of artificial sunlight other than the production of vitamin D or of a local inflammation in the skin has aroused protests from quarters which cannot be disregarded. The aspect of the subject first criticised, chiefly on economical grounds, is the tendency to choose ultra-violet light rather than foodstuffs rich in vitamin D for the prevention and cure of rickets. The physical method of treatment costs, according to the report, some 50 times more than the dietetic one. This point was well worth making in view of the vast expenditure incurred in the purchase of apparatus, and should be seriously considered by public bodies as well as by individuals. It must not be forgotten, however, that little is known of the mechanism whereby the vitamin promotes calcification. Certain children, for example, in whom there may be a defect in assimilation, are said to respond better to irradiation than to oral treatment. Moreover, the number of children suffering from minor degrees of fat indigestion is probably larger than is generally supposed. It is small points like these—very important although small—which must tell against the infallibility of general conclusions.

Interesting is the suggestion that in producing a local inflammatory reaction the artificial sunlight has no advantages over a mustard plaster, and we may here recall the existence of two distinct schools in light therapy. One set of observers do indeed challenge a comparison with earlier and simpler methods of producing hyperæmia, for their definite object is to cause an erythema, and they warn their patients that some degree of redness, swelling, tenderness, and subsequent peeling is to be anticipated. The other group regard such a reaction as a definite sign of over-stimulation and aim at sub-erythema dosage. This latter technique will be swept outside the realm of therapeutics if the future brings confirmation of the doubts expressed by the M.R.C. about the general beneficial effects of irradiation. But how exactly could these subjective effects be estimated? We cannot, for example, measure the exhilaration associated with a fine sunny day in basal metabolic or pulse-rates; it is surely independent of the movement of cold crisp air against the body surface, though stimulation may be enhanced by this contact. After a spell of cloudy weather, in summer as in winter, the appearance of the sun gives a pleasure, a relief from tension which is a common heritage of mankind. Tedious journeys undertaken by the rich in winter time, the grumbles of the people after a dull summer—it is unnecessary to reiterate the evidence of a real craving for sunshine, for none deny it. The point at issue is rather whether this craving can be satisfied, or somewhat satisfied, by artificial means. Many of the victims of the craving affirm that it can, and there is no more reason to doubt their subjective evidence than the impressions of their doctors. The brilliant artificial illumination now available in all civilised households has not been accepted as a substitute for sunlight, but the discovery that at least a few of the missing rays could be supplied from a new source naturally led to renewed experiments. A large number of people are convinced that irradiation appeases their longing for the sun in winter time and that it has definite tonic properties. What their need has been, and whether it will ultimately be expressed in terms of alteration in protoplasm or pigment, are still unknown. But because vitamin formation, pigmentation, and local inflammation are the only physiological changes as yet appreciable it is surely premature to infer that no others are derived from exposure to artificial sunlight. Experiments carried out by Dr. HELEN MACKAY in 1925 certainly appear to show that a belief in the general therapeutic value of ultra-violet light is unfounded—and confirmation of this comes from an experiment carried out on behalf of the Council by Dr. DORA COLEBROOK in the Willesden school area. The report of the M.R.C. points out that there are no published controlled experiments to set against these findings. That may be so, but there is a considerable body of clinical opinion in support of ultra-violet light, even though it is not supported by scientific evidence. And unfortunately scientific evidence in such a vague condition as general wellbeing must be difficult to obtain. Further, it is possible that other clinical observers might have drawn different conclusions from the experiments quoted, while the fact that in the experiments the "controls" were found to be less prone to minor respiratory ailments than the irradiated children suggests, if it suggests anything, that the rays were not entirely inert. The point may be granted that exercise and fresh air are greatly preferable to indoor sessions around a lamp. But is daily exercise in the fresh air always a possibility for schoolchildren in our cities during our long winters? The Council is equally doubtful as to the value of irradiation in the treatment of acute and chronic infections. It will probably be generally admitted that observations on the bactericidal power of the shed blood do not provide sufficient justification for the use of ultra-violet light in inflammatory conditions. But the same might be said of many other accepted methods of treatment, for we do not know with scientific certainty how far the in-vitro immunity

phenomena are accurate expressions of the powers of resistance of the living body.

While thus adducing some of the arguments in favour of a form of treatment which has not only achieved great popularity, but is believed by many clinicians to merit it, we are deeply impressed with the force of the criticisms levelled against its indiscriminate use. It would obviously have been desirable, had it been possible, to organise a trial of light therapy before accounts of its reputed benefits were so blindly accepted by the public. The method, however, has escaped from rigid scientific control, and its ultimate value can now only be assessed by the long and uncertain method of clinical observation. But the story of rickets, with which we started this discussion, gives ample reason for confidence that in the long run neither medical men nor the public can be deceived, and that if they continue to uphold any form of treatment its scientific value will eventually be established.

MEDICAL POLICY IN INDIA.

IT is with mixed feelings that we comment on two addresses, delivered by eminent members of the "independent medical profession" in Calcutta in December last, at a gathering styled the All India Medical Conference. Both Sir NILRATAN SIRCAR and Dr. G. V. DESHMUKH, whose addresses have now reached us, as their medical and other distinctions show, have attained a high status in the profession. Their opinions must command a hearing, and the animus displayed in their orations on this occasion is all the more regrettable on that account. What ground exactly the conference in question set out to cover is not apparent, but Sir NILRATAN, the chairman of the reception committee, and Dr. DESHMUKH, the president of the conference, concerned themselves almost entirely with medical politics in various aspects, and the relations of the independent profession with the Government medical services, and more particularly the Indian Medical Service. It is admitted at once that the work of the medical services, vitally useful as it has been in the development of the country, is open to adverse criticism in certain respects—the sort of criticism which may be levelled at all the European services in India. It is true that in the past the tendency of the official medical men has been to do the responsible work themselves, and to train up their Indian assistants in a subordinate capacity. It is also true that a certain amount of jealousy existed with regard to remunerative appointments and practice, and that vested interests and service claims were sometimes allowed too serious consideration. Then, again, students of the medical colleges and schools had certain real grievances. It has been too much the custom to change professors round from one subject to another, as convenience dictated, without sufficient reference to special qualifications, and teaching has sometimes suffered from this cause. Training in the later years of study and early post-graduate life was likewise adversely affected by the practice of filling house appointments in hospitals by members of the permanent subordinate services, and other handicaps exis ed which it will take time completely to get rid of. But when eminent Indian physicians say that the British in India have been unprofitable stewards—that Government has done practically nothing for education—that their neglect of irrigation has turned a land of peace and plenty into a home of stark want and fell disease—that the people are decimated by diseases of foreign importation—and that alien authority has only a sneer of indifference for genuine merit—it is unnecessary to deny the charges; we ask what place diatribes of this nature have in a medical conference?

The speakers came to more appropriate subjects when discussing the prospective Bill for the constitution of a central medical council for India, though even here racial bias becomes at once apparent in the terms employed. The proposed legislation, one of the most important objects of which is to put the Indian Empire in a better position to negotiate with other countries, and to maintain and enhance the reputation of its medical degrees in the eyes of the rest of the world, was regarded with quite unreasonable suspicion and the views of the conference will be widely reflected. It is suggested that the proposals are the sinister product of an alien bureaucracy (although the department directly responsible for the measure is almost entirely in the hands of distinguished Indians), and that the new central council will be subordinate to the General Medical Council of Great Britain. Hostility to the General Medical Council appears to be a sort of obsession, though people well qualified to know have pointed out over and over again that any intervention by that body in Indian affairs has always been confined to the protection of the interests of the general public at home, while its advice has been of the utmost assistance to India. Do the critics of the Council know what percentage of its work of recent years has dealt with Indian as well as with Colonial affairs? Constantly the President has himself dealt with important Indian matters, while the Council, as a body, has frequently been resorted to for advice on difficult phases of medical policy in India, when applications have always met with a ready and sympathetic response. The suspicious attitude which the spokesmen of the independent profession in India too frequently adopt towards the Council is therefore neither grateful nor well advised, and it is most unfortunate that the same attitude should be adopted with regard to the efforts of the Indian Government to create a body to regulate education, and to meet foreign criticism with regard to the status of the country's medical qualifications abroad. The same distorted and supersensitive nationalism is to be seen in the proposal put forward at the conference with regard to the establishment of chairs in Ayurvedic and Yunani medicine in the medical colleges—this as an extra burden on students who it is contended are already overweighted with a curriculum imposed on them largely through the malevolent machinations of the alien General Medical Council. Persistent ventilation of this matter has always led to the opinion among those who look temperately at the situation that the indigenous systems, however interesting from a historical standpoint, can have no place in a course of study devoted primarily to modern scientific medicine.

It is pleasant to note that Sir NILRATAN SIRCAR ends in a loftier and more reasonable vein by exhorting Indian medical and sanitary experts to devote themselves to investigating various social problems which call for attention; to study the factors which lead to excessive child and maternal mortality, the bearing of defective marriage customs on vitality and fecundity, and the effect of faulty diet and nutrition on various diseases. In these and other similar spheres racial jealousies and ancient differences may surely be disregarded. Meanwhile it is opportune to draw attention to the very liberal reforms which are now in course of introduction in the medical schools and colleges and attached hospitals. A cursory examina-

tion of the staffs will show to what an extent the leading educational posts are already held by Indians. Resident hospital appointments are also being increasingly thrown open to the newly qualified non-official men, and, as one of those whose addresses are here under consideration observes with not unnatural satisfaction, most of the lucrative practice of the larger towns has already found its way into Indian hands. These changes, one would think, should go far to meet the aspirations of independent Indian practitioners, and to reconcile them to the retention of what, after all, in relation to the total population of the country, is only an insignificant number of posts in the military and civil medical services, to serve the needs of the rapidly diminishing Europeans in the army and civil services. But apparently nothing short of the total exclusion of Europeans will satisfy these reformers. If no other reason existed against this course, we may remind them that Western science is a plant of comparatively recent growth in the east, and that it would be strange indeed if it were yet ready to flourish alone without external support.

THE NATURE OF FILTRABLE VIRUSES.

Two recent discussions at the Royal Society had for their subject the ultra-microscopic viruses infecting animals and plants. A large number of diseases in both categories are at the present time commonly attributed to viruses, though the definition of this class of pathogenic agents is not very clear. The character by which a virus is distinguished from other causes of infection are chiefly negative although attempts have been made to find more positive features distinctive of the group. By a virus is usually understood an infective causal agent which cannot be recognised or clearly seen by the microscope; this does not exclude the possibility that the virus particles are just visible in a stained film or by the dark-ground illumination. It has been generally held that all viruses are filter-passers—that is, consisting of particles too small to be stopped by an ordinary bacterial filter. It was this property which first attracted attention to the group, when IVANOVSKI filtered the virus of mosaic disease of tobacco in 1892, and LOEFFLER and FROSCH that of foot-and-mouth disease in 1897. It is now recognised that so-called viruses vary much in the ease with which they penetrate filters. Some like the two just mentioned pass very readily through such filters as a Chamberland III. or a Seitz disc under conditions in which these are quite impermeable to ordinary bacteria. The viruses of distemper and herpes can with proper precautions be obtained in the filtrates but are often retained by the candle. Certain infective agents such as that of typhus fever, which were at one time supposed to be filtrable, are now generally believed not to appear in the filtrate unless the conditions are such as also to allow passage to the smallest bacteria. Filtrability is not a function merely of the size of the essential particles in a virus but also depends on their tendency to adhere to the walls of the filter on account of their surface tension, electric charge, and other properties. In some cases, however, retention by a bacterial filter probably gives a useful indication of the average or minimum size of the active particles in the virus concerned. The rickettsia bodies associated in lice with the virus of typhus are usually at least 0·2 μ in diameter and do not pass through filters for that reason. It may be chiefly on account of the similar or slightly smaller size of the elementary bodies described by PASCHEN and by BORREL, and present in the lesions of vaccinia and fowl-pox, that the viruses of these diseases are not filtrable in the hands of most observers. BEDSON has shown that the virus of herpes, unlike that of foot-and-mouth disease, can be concentrated by centrifugation, and this, taken with the relative filtrability of the viruses, suggests that the particles in herpetic virus belong to a grade in size between that of vaccinia and foot-and-mouth disease. No evidence as to the filtrability of many plant viruses can be obtained because they have only been transmitted by grafting, never by injection.

The third negative property which characterises the group of viruses is the inability of the agent to grow on artificial media. The micro-organism of pleuro-pneumonia in cattle is probably often smaller than the rickettsia of typhus, but like this it is not now reckoned among the viruses as it produces well-defined colonies on solid media. Although the well-accredited viruses cannot be propagated in vitro, they can be shown to multiply in the animal host and often to increase rapidly at some favoured site in the body where the concentration may reach a very high titre, as in vaccinia and foot-and-mouth disease. Obligatory parasitism, then, is one of the most striking and distinctive characters of the viruses and it also presents a very troublesome obstacle to investigation. The absence of all knowledge of truly filtrable forms of life which are not parasitic is a fact which awaits explanation. It might have been expected that, if such minute forms really possessed independent life, similar agents capable of assimilation and multiplication in vitro would have been discovered by their chemical activities. It is only in the region where the size of the borderland viruses—e.g., those of typhus and vaccinia—is approached that facultative saprophytes such as the microbe of pleuro-pneumonia and Olitzky's *B. pneumosintes* are known. In consequence of the inability to secure multiplication of a virus except in living tissues, the idea has been put forward, especially by DOERR, that a virus may not be living but rather catalytic in nature. It is suggested that increase of the virus is due to the living properties of the host, which as the result of stimulation by a small amount of virus reacts by producing fresh virus in large quantities owing to an unwonted or pathological metabolic activity. The notion has recently been examined and commented on by BOYCOTT. This hypothesis has been especially fostered by the study of two virus-like agents, the lytic agent or bacteriophage discovered by TWORT and D'HERELLE, and the filtrable virus of fowl sarcoma. The former, which passes freely through a porcelain filter and resists exposure to a temperature of 60° C., is regarded by D'HERELLE as a parasite which lives and multiplies in susceptible bacteria. There is no doubt much to be said for this view which D'HERELLE supports largely on the ground of the adaptability of the phage to new bacterial hosts. It is, however, opposed by BORDET and by BRONFENBRENNER, and the virus is said occasionally to appear de novo in previously unaffected cultures. The filtrable virus of fowl sarcoma has a very strong claim to be considered an independent living microbe, and is indeed so regarded by GYE and many others. There are difficulties, however, in admitting the very similar mammalian malignant growths into the same category, especially since some of the latter can be produced at will by the use of tar and other chemical substances.

Little difference can be detected between the behaviour in the body of pathogenic bacteria and the

majority of viruses, but our knowledge, especially of the latter, is very imperfect. Important features of disease such as the incubation period, infectivity, and immunity reactions can be paralleled in the two classes, though some minor differences have been claimed in the behaviour of the antisera. The adaptation of the agent to new species of animals and plants by passage is a common feature of diseases which are due to viruses, bacteria, or protozoa. It has been possible to secure the multiplication of the viruses of certain diseases (vaccinia, Rous sarcoma) in cultures of living tissue in vitro, but this cannot be accepted as conclusive evidence of independent life. Research with unseen and uncultivated viruses is a very different thing to dealing with bacteria or protozoa. Every determination of the presence, potency, or increase of a virus must be made by tests for infectivity. The investigation of virus diseases of plants is in some ways still more complicated than when animals are concerned. Many plant viruses can only be transmitted by grafting and the proof that a plant is, or is not, a healthy carrier must be obtained by grafting it on a susceptible stock. The recent advances in ultra-microscopic photography applied to the study of viruses have not yet reached a point where they can give practical assistance. On the whole the evidence and balance of opinion, though by no means unanimous, are in favour of the view that most viruses are living agents, but on account of their peculiar qualities an irrefragable proof seems to be unattainable by existing methods.

Annotations.

"Ne quid nimis."

THE KING.

WE published in THE LANCET of March 9th the official bulletin issued from Craigweil House on March 2nd. Another bulletin was issued from the same residence in the evening of Saturday, March 16th, as follows: "His Majesty the King is steadily, though slowly, regaining health. In strength, vigour, and appearance improvement is definite. The weather is restricting the opportunities for going outside the house. The ray therapy is being continued." The bulletin was signed by Sir Stanley Hewett and Lord Dawson of Penn.

A LABORATORY SERVICE FOR INSURED PERSONS.

THE fact that while money can be found for almost any sort of treatment for insured patients none is available for diagnosis has long been recognised as one of the most serious deficiencies of the National Heath Insurance Acts. The necessity for a laboratory diagnostic service was recognised by the Royal Commission of 1924–26, and the demand for such a service has been growing in strength ever since, but on the plea of lack of funds the Government has taken no steps in the matter. Meanwhile various insurance committees have attempted to make such service available for patients under their charge. Their schemes have differed widely; some have been of such a nature as to throw upon the rates a charge which ought to fall upon insurance funds, others have depended upon arrangements between insurance committees and voluntary hospitals of a type which under the Act of 1928 became ultra vires. There seemed, indeed, to be a risk of the establishment of a series of totally unrelated schemes, without proper supervision, some of them illegal and the result being chaos.

It was partly with a view to meeting this threatened situation that the British Pathologists Association was formed two years ago. As a result of representations from this Association the British Medical Association decided to constitute a consulting pathologists group, which since its inception has been working to produce some practicable scheme for the provision of diagnostic facilities for insured persons. It is regarded as inevitable that the charges should fall for the time being at any rate upon the patients receiving the benefit of the service—that is to say, the patient pays the laboratory fees through his practitioner. Although it is essential for fees to be kept low, the group sees grave dangers in throwing such work open to free competition, with the possibility of fee-cutting and lowered standard of work. It has therefore drawn up a schedule of minimal fees for the ordinary laboratory procedures of general use in clinical medicine. These fees have been calculated on a basis of time and laboratory costs and are designed to provide a reasonable remuneration to a laboratory performing such work at full pressure. A list has been compiled of pathologists in charge of suitable laboratories who are willing to undertake this work at the standard rate of fees. The country has been divided into convenient areas, and insurance committees will, if the scheme is adopted by the representative meeting at Manchester in July, be notified of the pathologists within their area willing to undertake this work. The scheme as it stands will be of undoubted assistance to panel practitioners, but it suffers from the grave drawback of being financially dependent upon the insured patient, who for the most part is not yet educated to spend money on mere diagnosis. Accordingly the volume of work under the scheme at the outset may not be great. Such a service is, however, badly needed, and when funds can be found for its administration as part of medical benefit under the Insurance Acts the existence of a working scheme should save much trouble.

THE PREVALENCE OF APPENDICITIS.

So various are opinions on the incidence of appendicitis among non-European races that Dr. Elsa Uhlenhuth,[1] of the Tübingen School of Tropical Medicine, has made a special study of the literature in the hope of getting at the facts. The general impression is that native races suffer little from appendicitis, but Dr. Uhlenhuth is not sure that this is correct. The greatest mass of information comes from China, where it is the most experienced physician that reports most cases. Many do not come to notice, the Chinaman being slow to consult the foreign doctor, especially for abdominal trouble, for which these "foreign devils" are apt either to prescribe a starvation diet, very unpleasant to a Chinese, or an operation whose outcome is uncertain. The patient, therefore, trusts himself to his domestic remedies, notably opium, which at worst gives him the painless death which he prefers to a life of discomfort. Dr. Uhlenhuth notes that the reports consulted are seldom statistical; rarely does the reporter state what he means by "few" or "many." Much is said about diet being the cause of the disease, but little exact information is given about the diet concerned. There are some who say appendicitis is rare in non-Europeans by reason of the different anatomy of their appendix, but no such difference has been proved. The conclusion reached from this survey is that while appendicitis occurs in all races of men of whom we have information, although few figures are available to show relative frequency, it does seem to be less common in Indians than in English people living in India; also few cases have been reported from Africa. To provide a standard we may say that in the years 1924–26, among an average of 290,000 men in the Army and the Navy, case-rate per 1000 was as follows: (1) In the Army: officers, at home 9,

[1] Arch. für Schiffs- u. Tropen-Hygiene, 1929, xxxiii., 105.

abroad 7½, in all 8¼; other ranks, at home 5, abroad 4¾, in all 4¾. (2) In the Navy (officers and men), at home 4½, abroad 4¼, in all 4½. The figures for the two services together were: at home 5·0, abroad 4·6, in all 4·8, but, of course, many slight cases are included.

THE METABOLISM OF CHOLESTEROL

CHOLESTEROL plays a very important part in the body, being an integral constituent of all living cells, and particularly associated with the brain and nervous system. The importance of the group of sterols to which it belongs has been further emphasised by the recent discovery that irradiation of sterols leads to the formation of vitamin D. O. Rosenheim and T. A. Webster, it is true, showed[1] that cholesterol itself is not the precursor, but the closely related substance ergosterol which is contained as an impurity in cholesterol from animal sources and only with difficulty removed from it. In other respects, too, our knowledge of cholesterol metabolism is very incomplete. The substance is supposed to originate mainly in the vegetable kingdom, although a number of workers have shown that it can be synthesised by the animal organism. The cortex of the suprarenal gland plays an important part in this synthesis, but the nature of the parent substance remains obscure. Prolonged feeding on diets containing very large amounts of cholesterol causes a definite increase in the amount of this substance circulating in the blood plasma; J. A. Gardner and H. Gainsborough have, however, shown[2] that there is no increase as the result of a single meal. The change in the cholesterol content of the plasma during the process of digestion is taken to indicate the simultaneous occurrence of an active endogenous metabolism in which cholesterol takes part.

Accurate information concerning the quantitative distribution of cholesterol in the body is of comparatively recent origin, since suitable methods of analysis have only developed during the past 15 or 20 years. Most of the studies have centred round the determination of the substance in the blood, and its variation in health and disease, with a view to the possible use of chemical examination as a means of diagnosis. The results of such researches have not as yet made it possible to assign any very definite diagnostic value to these determinations except in certain cases. It is, however, generally recognised that in the later months of pregnancy, in certain forms of nephritis and nephrosis, in biliary obstruction and variably in diabetes mellitus, an increase occurs in the blood-cholesterol. On the other hand, the amount may be lowered in pernicious anæmia and in infective conditions, and these changes are so well marked that their occurrence is often unmistakable. Attempts to extend these observations to other conditions have in general been less successful, for the reason that the changes concerned, if any, are of smaller range and because our knowledge of the variation of the normal cholesterol content is incomplete.

Gardner has laid special emphasis upon the proportion of cholesterol present as the free substance and that present as ester. It has long been known that the cholesterol in the blood exists largely combined as esters, particularly in the plasma where the average ratio of ester to free substance may be of the order two to one. The ratio is variable, and various authorities do not agree as to the exact figures, doubtless due to the use of different analytical methods. On the other hand, the red blood corpuscles probably contain cholesterol mainly in the free state. Accurate determination of the combined cholesterol requires previous precipitation of the free substance with digitonin, a somewhat laborious method necessitating the use of 20 c.cm. of blood. Probably for this reason most workers have determined the total cholesterol, using a simple colorimetric method requiring only 1 c.cm. of blood. However, as Gardner points out, the implied assumption that free and combined cholesterol have the same significance is by no means proven. E. Goodall has recently exposed in our own columns[3] the slender basis for the assertion that there is a regular menstrual fall in the blood-cholesterol. In our present issue Gardner and Gainsborough describe the disturbance of cholesterol metabolism which occurs during pregnancy; in agreement with earlier observers they find a rise in the free cholesterol of the plasma up to a maximum at about the thirtieth week of pregnancy with a concurrent fall in the combined sterol. The occurrence of increased amounts of free cholesterol in the later stages of pregnancy has led to the assumption that the pituitary gland, which F. H. A. Marshall has shown to be increased in activity at this time, is the stimulus to the mobilisation of fat from the adipose tissues. R. Coope found that injection of pituitrin into rabbits caused a considerable increase of fat in the liver. Possibly the increased concentration of fat and cholesterol in the blood during pregnancy is necessary in order to supply the fœtus with these materials. Such questions as these are unanswerable until our knowledge of normal cholesterol metabolism is more complete than it is at present.

TULARÆMIA IN DOMESTIC ANIMALS.

SINCE McCoy and Chapin in 1911 first succeeded in isolating the organism of tularæmia (*Bacterium tularense*) from the lesions of infected ground-squirrels in California, it has been ascertained that the virus may be harboured by many different hosts under natural and experimental conditions. The first demonstration of human infection was made in 1914 by Wherry and Lamb in cases of ulcerative conjunctivitis accompanied by fever and glandular enlargement, but the disease as a clinical entity dates from observations in the State of Utah since 1908, or earlier on cases of what was known locally as "deerfly fever." It was not, however, until 1919 that Francis established the fact that these cases were due to tularæmia infection conveyed to man from jack-rabbits by the biting fly, *Chrysops discalis*. In 1923 the organism was isolated from infected rabbits exposed for sale in the Washington market, and was shown to be the cause of a condition, known to the trade as "rabbit fever," among rabbit skinners and dressers. Since then human cases have cropped up in many States of the Union and the disease has also been reported from Japan. In 1926 three fatal cases, almost certainly due to rabbit infection, were reported from Virginia. Besides other transmitting agents, infection may be conveyed by means of the wood tick, *Dermacentor andersoni*, which apparently can determine the continuance of an epizoötic among rodents and may possibly carry infection to man. Other animals susceptible to natural infection are the coyote and the wood mouse, but hitherto the condition has been rarely noticed in domestic animals, of which the calf, pig, and goat appear to be quite resistant, and it is only recently,[4] in the State of Montana, that the virus has been detected in the blood of dead and dying sheep, and in dermacentor ticks removed from the bodies. So long ago as 1923 heavy losses among sheep, coincident with high mortality among jack-rabbits, were observed in these districts, and now that their cause is recognised, the question naturally arises how far such conditions among sheep and rabbits are of importance to the general public, not only in the countries immediately concerned but elsewhere, and what danger, if any, there is of importation. Further work is necessary to determine whether the meat of slaughtered sheep is a possible source of human infection. It seems that the principal peril lies with those concerned

[3] THE LANCET, Feb. 23rd, p. 384.
[4] Parker and Dade: Public Health Reports of the United States Public Health Service, 1929, xliv., 126.

with the dressing of the animals for sale, infection being definitely possible through contamination of the hands and eyes with infected tissues or through the excrement and tissues of ticks. With sheep the chance that infection may reach the market and be a source of danger to persons in slaughter- and packing-houses and to the consuming public generally is more remote but cannot be excluded, especially if animals are slaughtered for immediate local consumption. The importation of the virus into this country is even less probable, but is by no means impossible.

A MEANING FOR SYNERGISM.

"SYNERGISM" is a term that has been freely and loosely used in connexion with anæsthetics. It is doubtful whether those who introduced the word in describing experience with anæsthetic drugs had a clear conception of what they meant by it, and it is obvious that most of those who have since talked of synergistic action have no such conception. We are glad to see that criticisms levelled against the very existence of what is presumably meant by synergism have produced a reply from J. T. Gwathmey[1] in which there is, at any rate, a definite idea of "synergism" as represented by the combined action of magnesium sulphate and morphine. Gwathmey claims, on apparently good clinical grounds, that the pain-controlling action of morphine is greatly prolonged when it is used in conjunction with magnesium sulphate. He does not claim an increased power for the action of the morphine but merely a prolongation of its effects. Here, at least, is something definite to go on, if in the future the term "synergistic action" is confined to the ability of one drug to prolong the effects of another. In the past their meaning in this connexion has been vague, different, and inaccurate. The word "synergism" might apparently just as well have been used to describe the ordinary sequence of "gas and ether," after morphine and atropine, as any other combination of sedative and anæsthetic drugs.

From the more general pharmacological aspect the inherent difficulties of the question of "synergism" have been aggravated by loose thinking and by a loose use of the term. It would be preferable if it were employed in its purely literal significance—viz., that two or more drugs when administered in combination *work together* in the sense that they do not antagonise each other. The result would then be the simple arithmetical summation of the effects of each individual drug. There are numerous examples of synergism of this nature in practical therapeutics. It is utilised, for instance, in the case of purgatives and diuretics to secure the summation of the desirable effects of several drugs, while the side actions are not increased or may even be neutralised. But synergism is often employed in the sense that the combined action of two or more drugs is greater than could be calculated from their individual effects. *Potentiation* in this case is the term much to be preferred. The best studied examples of this type of action are in the narcotic group, where there is a certain amount of evidence to suggest that when alcohol, chloroform, or ether are administered together the result is a simple summation of their effects, while the addition of certain alkaloids such as morphine and hyoscine gives considerable potentiation. But it must be recognised that in the commonest and most apparent example of potentiation—viz., "twilight sleep"—it is seriously doubted by competent authorities whether there is any real potentiation of morphine by hyoscine. Experimental evidence in support of potentiation is difficult to obtain, and it is still more difficult to explain its mechanism. But it is certain that the changes in the human body produced by disease often modify the effects of drugs to a remarkable extent, and there is nothing inherently improbable in the idea that one drug may so alter the condition of the body as to render it more susceptible to the action of another drug, though it may be impossible at present to explain how this happens.

VOCATIONAL GUIDANCE.

DURING the last ten years a considerable amount of research has been directed towards the parallel problems of vocational guidance and vocational selection—the discovery of the most suitable employment for the individual worker, and the selection of the most suitable workers for any given employment. The "square peg in the round hole" has become a synonym for inefficiency, and it is the object of this type of research to remove this anomaly, unfortunately so common because of the random manner in which many, perhaps the majority of, children leaving school drift into employment. Two bodies have been engaged in these investigations: the Industrial Fatigue Research Board, which is itself a branch of the Medical Research Council, and which began a number of inquiries into industrial conditions during the war; and the National Institute of Industrial Psychology, which was established in 1921, and has concerned itself chiefly with vocational problems. Both bodies have issued reports from time to time, and the latest brochure[1] records the results of an investigation, carried out by the former body for the latter, dealing with the "Use of Performance Tests of Intelligence in Vocational Guidance." Besides these official researches, much valuable work is being done by several large firms, who have appointed psychologists to work out the best methods of selection for the purposes of their own special work. Some local education authorities are also endeavouring to discover better means of advising children leaving school regarding choice of an occupation.

The problems are not easy of solution. For any efficient scheme of vocational guidance there must first of all be some grasp of the qualities of mind or skill required in different occupations; and, secondly, there must be some reliable scheme for testing these qualities in candidates. The difficulty arises from the complexity of human psychology, about which there is still far from universal agreement. On the whole there is now fairly general acceptance of the thesis that, running through all mental activities and conditioning them, there is a factor of general intelligence, known to the scientific psychologist as "g"—a factor varying in individuals according to the normal curve of variation. Besides this, however, there is a multitude of specific factors, specific to individual capacities and skills, memories and reasoning capacities, mathematical capacities, manual ability, mechanical constructiveness—to give only a few examples. There is still much difference of opinion whether in relation to mechanical trades there is a general mechanical ability contributing to them all, a general power to appreciate and deal practically with spatial relations; or whether there are only specialised capacities, functioning in one or a few definite directions. This point is discussed in the report now issued. The performance tests employed are well known to mental testers—the Porteus mazes, the cube imitation and cube construction tests, Dearborn's formboard, Healy's picture completion tests, Woodworth and Wells's substitution test, and a few others. All were found to correlate to considerable degree with "g," although not so closely as the more verbal types of tests of the Binet pattern. Specific factors played a larger part than in the Binet tests, but while certain correlations suggested that there was another general factor of "spatial relations" affecting success in several of these tests, it was not felt that the evidence was conclusive for any general non-verbal or practical ability factor. To use these tests, then, as a group from which to draw conclusions is impossible; each test must be taken separately,

[1] Medical Research Council: Industrial Fatigue Research Board. Report No. 53. H.M. Stationery Office. 2*s.* 6*d.*

its specific meaning sought for in order to estimate its vocational significance. A preliminary application of a few of the tests to groups of carpenters, fitters, electricians, and smiths appears to support the idea that they may be of value vocationally.

The results of this investigation are therefore somewhat limited, but the complexity of the problems for solution makes progress inevitably slow. The more empirical factory method of trying out tests to gauge capacity in a specific occupation may produce more rapid practical results, but for a thoroughly sound scientific basis and coördination of the work, investigations such as the present are essential. In addition they will make a valuable contribution to our understanding of human psychology, especially in its non-linguistic aspects, formerly somewhat neglected. It should scarcely be necessary to insist upon the importance of the factor of interest in psychology and in work. It is possible that the factors, interest and capacities, run more or less parallel, but the parallelism is not absolute. and vocational guidance schemes will have to guard themselves against the possible danger of placing a man in work in which he is not interested, assuming, that is, that the conditions of modern industry with its infinite subdivisions, allow any place for human interest.

THE RATIONALE OF THERAPEUTIC PNEUMOTHORAX.

WHEN Forlanini introduced artificial pneumothorax as a method of treating pulmonary tuberculosis, he said that a cure could only be obtained by keeping the lung in a state of complete immobility for two years or more. Murphy and his co-workers, on the other hand, regarded functional and not absolute rest as the essential, and it is now well known that many tuberculous pulmonary lesions can heal satisfactorily even when incomplete collapse, with respiratory movement of the affected lung, is maintained for a period. Stuart Tidey,[1] indeed, denies the possibility of complete immobilisation of the lung by induced pneumothorax, and considers that although rest is an important factor in the arrest of active disease of the pulmonary tissues, it is not the only one, and not the most potent. Remarking that no ulcer, whether on the inside or on the surface of the body, can heal if the edges are subjected to continued tension, he gives it as his opinion that healing of ulcerative pulmonary lesions can only be looked for if relaxation of the peripheral pull on the diseased area has been secured. This relaxation of peripheral tension may be brought about in various ways—e.g., by compression of the chest wall by strapping, or by special splints, by artificial pneumothorax, or by thoracoplasty. Nature herself tries to diminish the peripheral pull by making the chest wall contract over a fibroid lesion in the lung. In an original contribution [2] entitled Pneumothorax Expérimental, C. B. Udaondo and A. Vadone, of Buenos Aires, have produced some evidence which supports this contention that a collapsed lung is not at rest, and that the principal effect of pneumothorax is to diminish the distension of the pulmonary parenchyma. In an attempt to reproduce the conditions obtaining in a pneumothorax cavity, they placed the lungs of a freshly killed rabbit in a half-litre bottle, and tied the trachea to a tube passing through a rubber cork which hermetically sealed the bottle. Another tube connected the cavity of the bottle with a 10 c.cm. syringe, whilst a pneumothorax needle of proportionately reduced calibre was also passed through the cork into the bottle and connected it with a Küss pneumothorax apparatus and manometer. The investigators were thus able to set up either negative or positive pressures in the bottle, and so either distending or collapsing the lungs; at the same time they could imitate the rhythmic movements of respiration by moving the piston of the syringe. They found that even the smallest oscillations of the manometer corresponded to the movements set up by the distension and retraction of the pulmonary alveoli. It is wrong to suppose that, if a pneumothorax is present, the lung must necessarily be completely immobilised; Udaondo and Vadone show that when the lung is entirely collapsed it offers less resistance to an inspiratory dilatation than when it is distended—that is to say, that the manometric oscillations are deeper and respond more quickly to the least pulmonary movement when the lung is collapsed. They regard the term "average pleural pressure" as a theoretical figure obtained sometimes by calculation and occasionally by artifices of manometric technique. The lung is never subjected to a fixed pressure, as it responds to the least fluctuation of pressure taking place in the pleural cavity. But, being given these fluctuations, the figure which most accurately shows the degree of collapse is that which corresponds to the end of expiration.

OPHTHALMOLOGY IN RELATION TO RESEARCH.

IN an address which he gave to the recent Indian Science Congress at Madras Lieut.-Colonel R. E. Wright pointed out various directions in which ophthalmic research has of late advanced our knowledge of general as well as of ocular pathology. As an instance of the former he cites ophthalmoscopic observation of the retinal vessels, by means of which, he says, we are enabled to gauge, more accurately perhaps than by any other method that can be applied during life, the probable changes which take place in the cerebral vessels. The fact that these observations may now be recorded accurately and scientifically by means of photography enhances their value. The chief advances in ocular pathology in the narrower sense Colonel Wright finds in the invention of the slit-lamp, by means of which the nature of the anterior structures of the eyeball can be studied more in detail than before, investigations into the causation of cataract in connexion, on the one hand, with the chemical nature of lens protein, and on the other, with alterations in the fluid available to the lens for its nutrition. It is admitted that these investigations have not as yet advanced to the point of providing results clinically available. In connexion with trachoma the late H. Noguchi's bacteriological researches as to its cause are mentioned, though as yet his results lack confirmation by others. Other important works referred to as illuminating special branches of ophthalmology are Prof. Arthur Thomson's work on the anatomy of the human eye, Prof. A. Onodi's work on the nasal accessory sinuses, Miss Ida Mann's book on ocular embryology, published last year, which throws considerable light on the genesis of certain congenital defects, and the researches of W. S. Duke-Elder on the circulatory conditions of the fluids of the eyeball, which increase our knowledge of the pathology of glaucoma and foreshadow the possibility of advances in the future in the medical as opposed to the surgical treatment of that affection. Colonel Wright concludes with a reference to Sir John Parsons's recent work, "An Introduction to the Theory of Perception," in which the abstruse problems connected with the philosophy of vision are lucidly discussed.

THE SUPPLY OF DENTISTS.

THE Dentists Register for 1929 which has just been issued[1] contains 14,388 names, a diminution of 188 on the previous year. The number of names added by registration during the year 1928 was 261 in the British list, 1 in the Colonial, and 2 in the Foreign. Twenty-two applicants were registered under the

[1] London: Published for the Dental Board of the United Kingdom, 44, Hallam-street, W., by Constable and Co., Ltd. 12*s.*; copies for previous years, 1*s.*

Dentists Act of 1921, the others on account of registrable qualifications. Of the 703 names which appear last year and not this, 201 were removed from the Register on evidence of death, 3 by disciplinary action, and 499 for other reasons, including failure to supply notice of change of address or to pay the fee of £4 demanded annually for retention on the Register. During the year 251 names were restored to the Register after compliance with the regulations. Of the total number of registered dentists not quite one-half, or 6824, are registered with medical, surgical, or dental qualifications, while the remaining 7564 are registered under the provisions of the Dentists Acts of 1878 and 1921. The total of dental students registered in 1928 was 256, the number of entries having increased slowly but steadily since 1925, but the number is obviously not yet sufficient to neutralise the wastage. The Dentists Register differs from the Medical Register in providing a local list of names so that it may be seen at a glance what dental practitioners are available in any English town or Scottish burgh.

THE LOCAL GOVERNMENT BILL.

A BRIEF account is given in our Parliamentary Intelligence columns of the important proceedings with which the Report stage of this Bill in the House of Lords closed on Thursday, March 14th, when the question which has aroused the principal discussion—namely, the inclusion of the word "treatment" in the functions of the advisory committees was temporarily settled adversely. In a final amendment to the related clause Lord Dawson moved to add to the bodies which local authorities ought to consult "the medical faculty of any university which serves the area, and the duly qualified medical practitioners in the area," and argued that it would be an obvious advantage that the representatives of the faculties of medicine who were concerned with the higher laboratory investigations and various forms of research should be able to join many representations by way of conference with the council. As regarded the question of the duly qualified medical practitioners in the area, it must be borne in mind, he said, that the doctors who up to now had given their advice—and very excellent advice for they were admirable in their own domain of preventive medicine—amounted to about 1700 in England and Wales, while the doctors who were concerned with curative medicine numbered something like 28,000. From this he argued that "when they were going to add to the duties of these councils by assigning curative functions to the hospital work, there should be some representatives of those people who spent their lives in dealing with disease and that it should not be left too exclusively as heretofore in the hands of the very excellent men whose knowledge and experience was limited to preventive medicine." Lord Onslow, however, considered that these points were met by including in the committees those medical men who were conversant with hospitals and deprecated the addition of medical men, however eminent, whose connexion might merely be that of interest in medical education. He thought also that only confusion would be caused by the addition to the advisory bodies of medical men not connected with the hospitals. It will be seen, therefore, that Lord Dawson's efforts to bring into proper relation with the new hospital administration the experience and life-work of the general practitioner have ended in failure for the time being, but his vigorous representations may yet play an effective part at the final stages.

A VALUABLE YEAR BOOK.

WE have received from Messrs. Charles Griffin and Co., Ltd., a copy of the Official Year Book of the Scientific and Learned Societies of Great Britain and Ireland for 1928, which contains a record of work done in science, literature, and art during the session 1927–28 by numerous societies and Government institutions. This is the forty-fifth annual volume of a useful compilation, and deserves a larger measure of support than appears to be forthcoming from the societies whose work is recorded. Next year it is proposed somewhat to limit the scope of the issue by inserting lists not of papers read but only those which are published by the societies in question, and so become permanently available for reference. We hope that the publishers will receive the support necessary to enable them to continue what is one of our most valuable and most accurate works of reference. The price of the volume, which is well printed and indexed, is 18*s*.

THE KING has appointed Dr. William Macrae Taylor to be Surgeon Apothecary to His Majesty's Household at the Palace of Holyroodhouse, in succession to the late Colonel D. J. Graham.

Dr. Charles Herbert Hampshire, F.I.C., has been appointed by the General Medical Council to be Secretary of the Pharmacopœia Commission, and will take up his duties from June 1st. Communications intended for the Commission should be addressed to the Secretary of that body at 44, Hallam-street, London, W.1.

ACCORDING to the Students' Register, issued by the General Medical Council, the number of medical students registered during 1928 was 1363—namely, 545 in England, 577 in Scotland, 241 in Ireland. The total number is a substantial increase over last year's total of 1214, larger than any entry since 1922, and approaching the pre-war average of the five years 1909–13—viz., 1420.

WE regret to announce the death of Dr. Lionel Sells on Saturday last at the age of 52. One of the group of men who early took up the study of X rays in this country, he served in the South African War as radiologist attached to the Royal Army Medical Corps, and later joined the medical service of Uganda where he investigated sleeping sickness. As a result of his radiological work he lost several fingers of each hand.

Sir StClair Thomson has been elected Correspondant Étranger de l'Académie de Médecine, Paris.

A CONGRESS AT ZÜRICH.—As we have already announced, the Royal Institute of Public Health will hold a congress at Zürich in Switzerland next Whitsuntide, from May 15th to 20th. The preliminary programme has now been issued, and shows that the Congress will meet in seven sections—namely (1) state medicine and municipal and social hygiene; (2) industrial hygiene and industrial diseases; (3) child welfare, school hygiene, and women and public health; (4) pathology, bacteriology, and biochemistry; (5) tuberculosis; (6) climatology and sports hygiene, and (7) veterinary medicine and meat hygiene. The social events include a reception by the authorities of the Canton and City of Zürich on May 15th, and a banquet on the 16th, and there will be an opportunity of visiting large numbers of institutions and centres of interest in the neighbourhood. A tour on the lake, and tours to Rheinfelden, the Rhine Falls, and Schaffhausen are among excursions for those attending the Congress, whilst extensions are also being arranged, by the Swiss Government and railways, enabling participants to pay visits at reduced rates to Lucerne, Montreux, Leysin, and Montana, to Davos, Arosa, Innsbruck, Oberammergan, and Munich, or to Czecho-Slovakia. The address of the Institute in London is 37, Russell-square, W.C. 1; the arrangements for travel and accommodation are in the hands of Sir Henry Lunn, Ltd., 5, Endsleigh-gardens, W.C. 1. It is hoped that any who are interested will apply for membership of the Congress.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XXVI.—ALBUMINURIA.

TESTING the urine for albumin is an essential part of clinical examination, and will always remain so. It is true that an albuminuria may prove to be of little significance, but on the other hand it may be the determining factor in the diagnosis and prognosis of some important diseases, and its discovery imposes on the practitioner of medicine the duty of seeking further evidence to decide this very point.

The albumin commonly found in urine is a coagulable protein identical with the serum albumin of the blood, but other proteins may also be present —globulin, nucleo-protein, and on rare occasions a peculiar proteose known as the "Bence-Jones protein." For this reason the term proteinuria tends to replace the older term in some quarters, but this is neither necessary nor justified, for common usage has given a meaning to the term albuminuria which cannot be mistaken—viz., the presence in urine of a protein in sufficient amount to be easily demonstrated by the heat coagulation test or by one of the precipitation tests.

Tests.

We do not want merely to know which is theoretically the best test, but rather to practise the simplest and cheapest tests which are adequate for the purpose and to understand their variations and fallacies. Protein can be demonstrated by coagulation reactions, precipitation reactions, and colour reactions, and there are literally hundreds of methods and reagents available for the purpose. Colour reactions cannot be applied directly to urine, so those in most common use are the heat and acetic acid test, Heller's cold nitric acid test, and precipitation by salicyl-sulphonic acid, trichloracetic acid, phosphotungstic acid, hydroferro-cyanic acid, or picric acid; and for globulin and nucleo-protein dilute acetic acid in the cold.

For ordinary practice the most satisfactory reagent is probably (1) *salicyl-sulphonic acid*. The substance is a non-corrosive white powder exceedingly soluble in water, keeps well in solution, and is easily carried about. In testing for protein a few drops of a saturated aqueous solution of the acid are added to urine in a test-tube, and if protein is present a white precipitate is formed, varying from a faint opalescence to a dense white curd according to the amount. It should be noted that urines do not give the test unless the reaction of the mixture of reagent and urine is acid, but obviously it is only in very few cases of exceptionally alkaline urines, such as results after taking large doses of alkali, that protein could possibly be missed. In such cases the difficulty is overcome by adding a few drops of acetic acid to the urine before adding the reagent.

For routine hospital work, and where it is desired to learn something of the nature of the proteins present, the urine should be always tested also by (2) the *heat and acetic acid test*, and by (3) the addition of 4–6 drops of 20 per cent. acetic acid without heating. The heat coagulation test is necessary for the detection of the Bence-Jones protein, which appears almost as soon as the test-tube is warmed (50–55° C.), and almost disappears on boiling. The dilute acetic acid in the cold test is necessary for the detection of globulin, which rarely may be present without much albumin, especially in my experience in asthma and allergic diseases, and appears slowly as a white cloud about five or six seconds after the addition of the acid. The quantitative estimation is rarely necessary, but if required, the well-known Esbach's method is sufficient.

It is usual to record the amount of albumin from the qualitative test in some such manner as this. (*a*) Faintest possible trace—an amount shown by a faint opalescence recognisable only when compared to a test-tube of untreated urine seen against a dark background. (*b*) Trace—an opalescence seen easily against a dark background. (*c*) Fair amount—a distinct curdy precipitate. (*d*) Large amount—a dense precipitate. A trace of albumin corresponds to less than ½-part per 1000, and a large amount to more than 5 parts per 1000 on the Esbach scale.

To summarise, testing for albumin is best done by putting the urine into four test-tubes. The first of these is left untreated, and used for comparison. The second is treated with 5 or 6 drops of salicyl-sulphonic acid solution, the third by heating and adding a few drops of acetic acid, the fourth by the addition of 5 or 6 drops of 20 per cent. acetic without heating. Comparison of these tubes will show the relative amounts of total protein, heat coagulable albumin, and globulin.

The Meaning of the Result.

It is now well recognised that in itself albuminuria is not necessarily a sign, or even a warning, of disease of the kidney. It may arise from the presence of pus, spermatozoa, or urethral secretion in the urine, but apart from these a group of causes may give rise to intermittent or temporary albuminuria which cannot be regarded as a sign of any disease. These "functional" or "physiological albuminurias" include a variety known as "orthostatic" or "adolescent albuminuria." A complete and satisfactory explanation has never been given for these forms, but they may result from exposure to excessive cold, from excessive exercise, from taking certain drugs, or from some unimportant constitutional factor in rapidly growing adolescents. H. H. Bashford has had an opportunity of examining a group of these cases after 20 to 30 years, and reports that they showed no greater liability to disease or sickness than the control groups who had no albuminuria in adolescence. He reports also that in about one-fifth of the cases the condition may persist into the third decade of life, and that the children of these subjects are likely to show the same symptom.

To assess the significance of albuminuria it is thus necessary to know: (*a*) the age and history of the patient; (*b*) something of the nature and amount of the protein in the urine; (*c*) whether the albuminuria is constant or intermittent; (*d*) if there are any other signs of kidney diseases, which in their order of importance are œdema, red cells in the urine, pyuria, impaired renal function tests and casts; (*e*) if general examination reveals any cause of the albuminuria, the chief of which are general arterio-sclerosis, acute infections, acute allergic disorders, heart diseases, liver diseases, chronic toxæmias from syphilis, tuberculosis, sepsis, and pregnancy.

Keeping these various points in mind it is possible to conduct an examination which would yield sufficient evidence to decide whether the albuminuria is (1) an innocent functional albuminuria, (2) due to kidney diseases, or (3) due to a general disease or toxæmia. In general terms it may be stated that when the protein is albumin or globulin, is intermittent and not constant, is not accompanied by the presence of blood cells, pus, casts, or œdema, and is not to be accounted for by obvious evidence of general disease or toxæmia, and the patient is under the age of 35, it is reasonable to presume that the albuminuria is a functional one of no importance.

Age and History of the Patient.—An albuminuria in apparently healthy new-born infants is common and of no importance, since it disappears after six or seven days. In later infancy and early childhood it is again common, but is then pathological and usually denotes either kidney disease or latent sepsis, especially congenital syphilis, tuberculosis, middle-ear disease, and skin sepsis. From later childhood to the age of 35 the various forms of functional albuminuria are common. After that age albuminuria is

probably always due to some pathological cause, but in practice, if it is the only sign of disease, it requires no drastic treatment.

The history of the patient may be helpful, but a short transient attack of acute nephritis or of scarlet fever five or ten years earlier must not be regarded too seriously, for an inflammatory lesion of the kidney lasting only a few days will have caused no permanent damage to the kidneys. I have followed cases who have had repeated attacks of hæmorrhagic nephritis for more than ten years without any apparent damage to the kidney, the urine remaining free from albumin and other signs in the intervals.

Nature and Amount of the Protein.—The rare occurrence of Bence-Jones protein or of globulin *without* any albumin can first be disposed of. If a Bence-Jones protein is present, the patient is likely to be suffering from a new growth of the bones with diffuse secondary deposits, probably of the nature of myeloma.

If globulin only is revealed by the acetic acid in the cold test and there is practically no albumin coagulable by heat, some transient condition, such as asthma or some form of functional albuminuria, is suggested. Further than this we cannot go, for when both albumin and globulin are definitely present there is no significance in the relative amounts of these two substances.

The amount of the albumin is of little help. Certainly, when only the faintest possible trace is found, it can be disregarded, and even as much as 5 to 10 parts per 1000 may be present in an entirely innocent case of functional albuminuria.

Constant or Intermittent Albuminuria.—It is o great importance to find out whether or not the albuminuria is constant in all specimens. A series of two-hourly specimens should be examined ; when albumin is entirely absent during rest, and returns when the patient resumes the erect posture, it can be presumed to be functional. Confirmation of this can be sought by observation of the effect of a large dose of alkali or of calcium on the albuminuria. When the albuminuria disappears as a result of those measures, the patient is unlikely to be suffering from organic kidney disease.

Other Signs of Kidney Disease.—In all cases a careful and consistent search for red blood cells should be made, since these are the chief sign of inflammatory lesions in the kidney. In cases of parenchymatous tubular nephritis (nephrosis) there will be no hæmaturia, but œdema or a history of œdema will be found. On the other hand, an occasional hyaline or epithelial cast is not to be regarded too seriously, for they may be present without any kidney disease.

Renal function tests are not likely to be of great value in the doubtful cases, for it is in these very cases that the albuminuria will precede that degree of impairment of the renal function necessary to affect the efficiency of the kidney. But it is always wise to estimate the urea concentrating power of the kidneys and the blood-urea. If the urea concentration is below 1·8 per cent. and the blood-urea above 40 mg. per 100 c.cm. definite renal damage can be presumed.

General Examination.

Chief attention should be directed to the condition of the arteries, heart, and blood pressure. In patients with primary arterio-sclerosis and hypertension the presence or absence of albuminuria is one of the best guides to prognosis. So long as they remain free from albumin it is relatively good, but with the appearance of constant albuminuria the outlook is grave.

Albuminuria may result from so many febrile infections and general diseases that its significance under these circumstances is not likely to be mistaken. Its association with pregnancy is also well understood, and it is now widely realised that if it appears during pregnancy special antenatal care must be exercised and repeated examinations must be made in case it is a sign either of pre-eclamptic toxæmia or of nephritic toxæmia.

When so much has been claimed for latent focal infections as a cause of many obscure diseases, it is natural that these should have been suspected in cases of albuminuria where there is no other obvious explanation. It is certainly true that chronic bone infections, syphilis, and caseous tuberculous glands may so affect the kidney as to produce what might be called a toxæmic albuminuria. Probably there is some tubular degeneration of the kidneys in these cases, and if it is an albuminuria which is more or less constant in all specimens, it is rational to deal with any obvious focal infection. But always it must be remembered that if the patient is under 35, has no red cells in the urine, and appears to be otherwise in good health, the probability is that the albuminuria is an innocent functional affair. Every person passes albumin at some time or other, and at any given time it can be found in from 5 to 10 per cent. of whatever group of healthy individuals the observer may examine.

CLEMENS PIRQUET AND HIS WORK

AS DIRECTOR OF THE VIENNA UNIVERSITY KINDER-KLINIK, 1911–1929.

BY the untimely death of Prof. Clemens Freiherr von Pirquet in Vienna on Feb. 28th the medical faculty of that University loses at once a distinguished professor and a rare personality. His death will also be mourned by a large circle of English and American friends and colleagues, for, even at that most cosmopolitan of Universities, Pirquet was remarkable for a catholicity of interests and sympathies which knew no barriers of race, religion, or nationality.

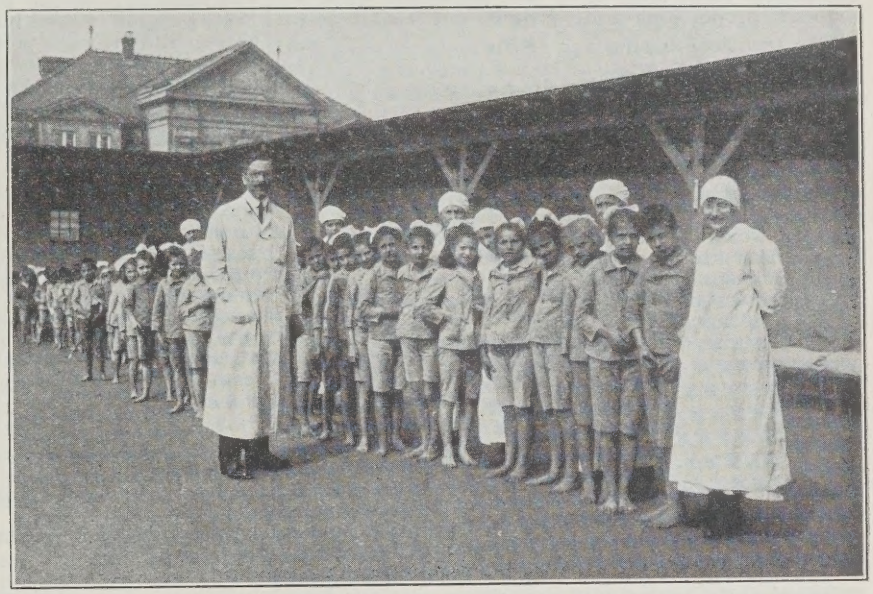
Clemens v. Pirquet, one of the younger sons of a Roman Catholic family belonging to the Austrian landed aristocracy, was born in 1874 at the village of Hirschstetten near Vienna, and was originally destined for the Church and educated for that purpose. This plan was, however, abandoned, and after studying at the Universities of Innsbruck, Vienna, and Graz he graduated in medicine at the latter University and shortly afterwards became assistant to Prof. Theodor Escherich, then Director of the Vienna Kinderklinik.

Pirquet's many important contributions to medicine, both as scientist, physician, and organiser, are especially notable for the originality and independence of thought they display. His early scientific work was devoted to bacteriology and immunity, more especially to the phenomenon to which he gave the name of Allergy, the condition in which an animal becomes supersensitive to foreign proteins, especially those derived from infecting microbes. To this period belong his important researches on serum sickness (Serumkrankheit) and on the immunological reactions following infection with tuberculosis, including the studies which led to the publication in 1907 of the skin test for the diagnosis of tuberculosis which bears his name. The analogous work with diphtheria carried out by his colleague and famous pupil Schick owes much to Pirquet's teaching and example. The reputation thus achieved was probably the cause of the invitation to the Chair of Pediatrics in Baltimore, which Pirquet accepted in 1908 and held for about 18 months. Then followed two years as Professor of Children's Diseases in Breslau, after which, in 1911, he was called to Vienna as Director of the University

Kinderklinik and successor to his old chief Theodor Escherich.

The magnificent Kinderklinik of the Vienna University was just completed when Pirquet took up his new duties there. In its present form it may be regarded as an expression of the genius of its first Director, not only in its material perfection but in the manifold nature of its activities and the spirit with which it is animated. It would be hard to find an institution where a real devotion to scientific research is combined so perfectly with an assidious care for the welfare and happiness of the sick children and with an affectionate consideration for the medical and nursing staff of every grade. It has been said that Pirquet transformed the ward maids into nursing sisters and these further into scientific colleagues. The vast series of investigations upon human nutrition which have occupied the attention of the Director and his assistants during recent years would have been impossible without the intelligent coöperation of his nursing staff. The results of his theoretical researches upon the nutritive requirements of the child at different ages and under differing conditions of sickness and health were applied conscientiously to the nutrition of every small patient. The hospital kitchen became the laboratory for this important work, and was one of the most impressive departments of the Klinik, never omitted when Prof. Pirquet conducted guests on a tour round the hospital. When asked how he succeeded in making his kitchen the instrument of scientific precision by which his "Nem" System could be applied, he would reply that the first step had been to place it in the charge of his most competent ward sister.

FIG. 2.



Prof. Pirquet with the children in the sanatorium on the roof of the Kinderklinik.

The "Nem" System.

Theoretical objections can be brought against Pirquet's "Nem" system, as for example, in the rejection of the calorie as a measure of nutritive value for a new arbitrary unit—viz., the "nem" or food value of 1 c.cm. milk (0·67 calorie). No one, however, who has seen the "Nem" system in working, can deny its success in practice. For in this system the nutritional value of foods is assessed against a *standard which can be seen and handled.* In the kitchen, where the nursing staff received an important part of their training, the working unit, 100 nems or 1

FIG. 1.

Prof. Pirquet and his assistants at the Vienna University Kinderklinik, 1920–22. (From left to right): E. Nobel (Vienna), K. Kassowitz (Milwaukee), H. Wimberger (Salzburg), Prof. Pirquet, B. Schick (New York), W. König (Vienna), E. Mayrhofer (Zagreb), R. Wagner (Vienna).

hectonem, is visualised as 100 c.cm. of milk, seen in the graduated cylinders which function as the ordinary kitchen measures. The newest probationer soon realises that the addition of 8 g. of sugar or cereal in the preparation of an infant's food increases the food value of the meal by 50 per cent. The dishes destined for the older patients are prepared on similar quantitative lines, and the weighed portions served later in the wards secure that each receives a diet of the calorie value ordered by the physician, with the requisite proportions of fat, protein and carbohydrate.

The practical application of Pirquet's Nem system was fully developed by the end of the war period and was thus available for the time of suffering through which Vienna passed in the years from 1918 to 1922. When in 1919 the mass-feeding of the children was undertaken by the American nation, Pirquet was entrusted with the entire organisation of this gigantic enterprise, which involved the provision of at least one meal daily for 160,000 children of school age. In this work he was untiring, and his energy and hopefulness stood out in marked contrast to the spirit of despair and apathy which, at that period, brooded over the city. He was in truth, a "diffuser of life" in that time of trouble. Any morning, after discharging his duties at the Klinik, the Professor, accompanied by two of his assistants, might be seen hurrying to the headquarters of the "Amerikanische Hilfsaktion." His efficient organisation secured that the general scheme, conceived in the Kinderklinik, was faithfully carried out even in the most distant distributing centre. After a medical examination and assessment of their nutritional state by the series of body measurements laid down in Pirquet's System of Nutrition, the selected children received meals of suitable nem (calorie) value for their age. The kitchens, in some of which 10,000 meals were prepared daily, were run in accordance with the Nem system, directed by well-educated women trained in the kitchens of the Kinderklinik. The system employed is worth the careful study of all interested in school or communal feeding.

The Hospitality of the Kinderklinik.

The hospitality shown to foreign students in the Vienna Kinderklinik under Prof. Pirquet has become proverbial. A striking example is the welcome extended to the group of English women who, under the auspices of the Lister Institute and the Medical Research Council, went to Vienna for the purpose of studying deficiency diseases in the years following the war. Owing to their recent isolation, the Vienna scientists were ignorant of the new work showing the importance of vitamins in nutrition, and Pirquet was no exception, being entirely preoccupied in the quantitive aspect of nutrition, which presented such appalling problems at that time. Nevertheless, the British workers were warmly welcomed and received every assistance in their studies upon scurvy in infants and older children. Later, they were invited to undertake a joint experimental and clinical investigation on rickets and its relation to diet, this disease having become almost universal in the Viennese infants at that time. A complete ward, with nursing personnel and medical supervision, was placed at the disposal of the research, and, in addition, the scheme enjoyed the resources of the perfectly equipped X ray department and the devoted collaboration of the X ray specialist. At one time or another the help of every department of the Klinik and of almost every member of the staff was made available for the work. These privileges were freely given for the space of two years, and researches were thus made possible which surely could hardly have been carried out by guests in any other institution.

The love and devotion which Pirquet inspired in his staff, both medical and nursing, was touching. In his Klinik he was an adored king, yet no detail seemed too trivial for his personal attention, if it afforded an opportunity for some kindly act. He was very fond of children, and a favourite department of his Klinik was the large ward which he arranged on the roof for sanatorium treatment of 150 tuberculous children of all ages. The little patients would remain in this ward for periods extending to a year or more, and their life was arranged with due regard to their education and well-being in every direction. An attractive feature every morning was the long procession of children winding down the staircase from the roof, singing Austrian part songs on their way to the school, which was held in a special pavilion in the Klinik garden. Prof. Pirquet entered into the life and amusements of these children with perfect sympathy, and was often the central figure at their little festivities. At carnival time they, no less than the more fortunate children in the city, must have a party, and the Professor would often put on a fancy dress to add to the joy and gaiety of the gathering.

Prof. Pirquet was a tall handsome man and possessed great charm of manner. He was a fine linguist and spoke English perfectly and idiomatically. In spite of his success and enviable position he remained very simple in spirit and manner, and would display his pleasure at a birthday greeting from one of his small patients no less than when receiving some important honour or distinction from outside. Those who have enjoyed the hospitality of the Vienna Kinderklinik will find it difficult to visualise it without the gracious figure of its well-loved chief.

HARRIETTE CHICK.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Anti-accident Week.

A SO-CALLED Anti-accident Week has just been held in Berlin. Lectures were given in schools, factories, and hospitals on the way to prevent accidents in industry, the home, and the street; special pains were taken with the instruction of children; and posters were seen everywhere in tramways, buses, railway carriages, public buildings, restaurants, and theatres, with advice on how to avoid accidents and on the need for effective first-aid. The cinemas contributed to the campaign by giving special performances. Figures published in the newspapers show that last year there were about 2 million accidents in Germany and that nearly 24,000 of these were fatal, giving an average daily mortality of 64. Thirty per cent. of them occurred in factories, the remainder being in streets and at home. The campaign was carried out under the patronage of the Ministry of Labour, the German Insurance Office, the employers' associations under the Workmen's Insurance Act (Berufsgenossenschaften), and the police.

Combating Noise.

The well-known aurist, Dr. Peyser, lately drew attention in the Medical Chamber to the noise in Berlin and its influence on the health both of the public at large and of individuals. He distinguished three kinds of noise: traffic noise, factory noise, and home noise. Continuous noise in factories leads, he said, to direct injury to the inner ear, whilst noise in traffic and in the home may cause serious disturbance to the nerves of sensitive persons. Most of it can, he thinks, be avoided, and in this connexion he alluded to the police regulations by which motor-cars have to give signals at every street-corner by horns, and to the signals of the fire brigade which consist of a continuous tintinnabulation, together with blasts on a special horn. The use of gramophones and loud-speakers at open windows is a recent but not less disagreeable nuisance. Dr. Peyser said that Berlin was the noisiest city in Europe, and on his suggestion the Chamber adopted a motion inviting the police to take measures against noise, especially in the neighbourhood of hospitals and sanatoriums.

Illuminated Door-plates.

To make it easier to find a doctor in urgent cases the door-plates of medical men in several towns have been lighted at night. This practice has not met with general approval, and in Berlin the Medical Chamber are of opinion that it is contrary to the recognised rules of the profession. They point out that in Berlin medical aid can be obtained in cases of accident through the municipal first-aid stations established throughout the city. In Hamburg a list of doctors prepared to do night service is kept by the police, and patients who want urgent aid have only to apply at the next police-station or approach a police-patrol which will at once fetch the next medical man on the list. It is reported that many of the junior medical men in Hamburg earn a livelihood in this way.

Sleeplessness in School-children.

Herr Klos, headmaster of a Berlin municipal school, says that about a third of the children at his school are still sleepy during the first morning lesson —many of them so sleepy that they cannot follow the lesson at all. On investigation he found that these children, although going to bed very early, are unable to sleep, and he has inquired into the causes of their sleeplessness. The answers were manifold: some complained of the noise of the wireless used by their parents, some of the noise made by neighbours doing night work. On the other hand, some said that the silence of the night made them nervous; they were afraid of burglars or ghosts. Some were disturbed by the light falling through the windows, or by barking dogs, others said that they were still thinking and ruminating upon school and other matters. A good many of the children were regarded as "obviously neurasthenic"; they complained that their bed coverings were too hot, that they had dreams, or that they were sweating and excited. Such cases ought to be examined by the school medical officer, whilst in the others there are external causes to be removed.

The Medical Profession and Trade Tax.

The Government has had the intention of including members of the medical profession among those who are obliged to pay trading tax. This intention has caused some alarm and the medical faculties of the German universities have petitioned against it, saying that in consequence of the measure doctors would be regarded by the public as tradesmen. The tax itself is fairly high but its direct financial effect would bear little proportion to the harm it would do. The Medical Chambers also have protested and it is reported that the plan has been dropped. It may be remarked that the provisions regarding medical practice are all to be found in the Trades Act of 1869, so that the Government's intention is not quite illogical. But the profession has long wanted to have medical practice taken out of the Trades Act and made subject to a special law, as is the practice of law and other liberal professions.

According to a report by Dr. Burgsdorf from the German Statistical Office the fertility of German mothers decreased by 26 per cent. between 1913 and 1926; the 1913 figure was itself 50 per cent. below that of 1875. In 1900 there were still 300 children born from each 1000 married women capable of child-bearing, but the annual figure fell to 138 in 1926. It cannot be expected that this state of things will change in the near future, and Burgsdorf thinks that the average of 3·4 children per married woman is insufficient to maintain the continuance of the German people without being supplemented by illegitimate births.

From an investigation by the German Health Office it appears that some of the cigars advertised and sold as not containing nicotine, or only a small and innocuous quantity of it, have proved to contain more nicotine than ordinary cigars. The advertisement of such cigars may thus be regarded as unfair competition and can be punished by law.

For the sake of rural school-children who often have to go a long way to the next dentist, the provincial school and health authorities of Rhenish Prussia have provided a motor-car fitted out as a dental dispensary. This motor-car contains an operating room with all the necessary dental appliances. The appliances are driven by electricity, the car containing a cable which may be connected with the nearest light cable. There is an appointed school dentist travelling with the car to the different places where the school-children are sent to him for dental examination and treatment.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Deaths of Physicians.

THE American Medical Association has issued its annual analysis of the information derived from obituary notices of its members. The average age at death is found to be 63·1 years, a slight gain on previous years. According to United States life-tables the expectation of life in this country at age 20 was 64·3 years in 1910 and 66·2 in 1922. It would be interesting to see a life-table constructed from the data obtained by the American Medical Association for the 2792 deaths that occurred among its members last year. Heart disease is the leading cause of death as might be expected, since it is overwhelmingly the most important cause in that part of the general community which survive the first two decades of life. It might at first sight seem strange or significant that tuberculosis should take as low a place as eighth on the list. However, if we consult a table showing for the registration States the chances, at a given age, of dying eventually from a given disease,[1] and select the age-group 15–25 (since all doctors must have reached that group before becoming doctors), it appears that here tuberculosis takes seventh place. Using this method of comparison it will be found that the causes of deaths among physicians are not greatly different in their relative importance from the causes of death among their patients.

Ventilation of School Buildings.

When the New York State Commission on ventilation reported six years ago that they had found less respiratory sickness among the children in window-ventilated schools than in the schools that were mechanically ventilated, a controversy was started that has scarcely died down yet. Many States have outlawed the simpler method in their building statutes—and naturally the engineers were not inclined to submit without protest to a decision that seemed to condemn all their efforts. They desired that future investigations should take physical standards (as temperature humidity and air environment) rather than absences of pupils attributed to "colds." However, the public health investigators have remained firm in their contention that the final criterion is the health of the school-child, though they agree to the desirability of measuring the physical conditions and correlating their measurements with the practical findings in health. Subsequent investigations, including one that is just reported by an engineer of the public health service,[2] have amply confirmed the conclusion that window ventilation is associated with a lower rate of respiratory sickness. It is, of course, admitted that what holds true for classrooms is not necessarily true for large halls. Yet there is evidently some factor present in window

[1] Amer. Jour. of Public Health, 1928, xviii., 880.

ventilation that is either unknown or whose value is not properly appreciated.

Mental Hygiene.

The first international congress of mental hygiene is to be held in Washington, D.C., during the week of May 5th–10th, 1930. The secretary of the American National Committee, Mr. Clifford W. Beers, has been elected secretary-general of the congress. An administration office has been opened at 370, Seventh-avenue, New York City, in charge of Mr. John R. Shillady. British members of the sponsoring committee are Dr. J. L. Birley, Sir Hubert Bond, Dr. A. Helen Boyle, Sir Farquhar Buzzard, The Countess of Chichester, Sir Maurice Craig, Lady (Horace) Darwin, Miss Evelyn Fox, Dr. Edwin Goodall, Dr. J. R. Lord, Dr. H. C. Marr, Dr. Bedford Pierce, Prof. George Robertson, Sir Leslie Scott, Lord Southborough, and Dr. Henry Yellowlees.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Sanatoriums and Tuberculosis.

AT the annual meeting of the Royal National Hospital for Consumption Prof. T. G. Moorhead took the opportunity of suggesting what place sanatoriums should take in the fight against tuberculosis. Recent pronouncements, he said, had led many to think that sanatoriums had become obsolete, but they were still the first line of defence. What had failed had not been the sanatoriums, but the provision of after-treatment. It had been estimated that there were in the Irish Free State 18,000 fewer sufferers from tuberculosis than in 1912, and in the accomplishment of that change sanatoriums had certainly played a part. There was still inadequate sanatorium accommodation. He urged the establishment of a tuberculosis colony in the Free State, but it should not be established in connexion with any single institution, but should be open to patients from all sanatoriums.

The Hospitals and Treatment for School-children.

For some time past negotiations have been going on between the city hospitals and the City Commissioners of Dublin regarding the treatment of school-children for disabilities discovered in the course of medical inspection. The Leinster Branch of the British Medical Association tried to secure unanimity among the staffs of the hospitals about the remuneration they would accept for specific services in the hospitals. Certain grouped hospitals have, however, agreed to conditions which do not meet with the approval of the Leinster Branch, and it is suggested that these terms have been agreed to without the authority of the members of the staffs of the hospitals. At a recent meeting of the branch a resolution was unanimously carried withholding approval of the arrangements on the grounds that the remuneration mentioned was quite inadequate for the services rendered, and that the correspondence submitted to it bore no evidence of the terms having been accepted by the medical staffs of the hospitals concerned.

A Medical Recruit to the Dáil.

Dr. Thomas F. O'Higgins has been elected deputy for the northern division of the city of Dublin by a narrow majority. His entry to the Dáil should add strength to the already important medical group of deputies. Both divisions of the city of Dublin now have a medical man among their representatives. Dr. O'Higgins is a son of the late Dr. T. F. Higgins, of Stradbally, Queen's County, and a brother of the late Mr. Kevin O'Higgins, Minister for Justice. He took his qualifications from the Royal Colleges of Physicians and Surgeons in 1914, and subsequently served for some years in the Royal Army Medical Corps. For the past few years he has been Director of the Army Medical Service of the Irish Free State. He has been a competent administrator, and it is well that while the public loses his services in one capacity it secures them in another.

MEDICAL RESEARCH COUNCIL.

ANNUAL REPORT FOR 1927–28.[1]

THE report for the year 1927–28 to the King in Council from the Committee of the Privy Council for Medical Research incorporates the fourteenth annual report of the Medical Research Council. The total sum at the disposal of the Council last year was £166,000, including the Parliamentary grant of £148,000 and an additional £18,000 from unofficial public and private sources. It is noteworthy that less than 6 per cent. of the total expenditure was spent on administration, that roughly one-third has been allocated to the maintenance of the National Institute for Medical Research and its associated laboratories, and that two-thirds has been paid out in salaries and grants for expenses to workers in other institutions.

Liaisons throughout the Empire.—During the year liaisons have been established or fostered between the Medical Research Council and other official research organisations in the Empire, notably by the visit of their secretary, Sir Walter Fletcher, to India, and by the coöperation of Prof. Lyle Cummins, of the Tuberculosis Committee of the Council, with the corresponding committee of the South African Institute for Medical Research. The National Research Council of Canada is keeping the Medical Research Council informed of the progress of large-scale experiments designed to test the value of the B.C.G. vaccine, and investigations carried out in the colonies, protectorates, and mandated territories is being brought effectively into relationship with those in progress in Great Britain by the work of a newly established Colonial Medical Research Committee. The Empire Marketing Board has coöperated with the Council in investigating the nutritive values of various foodstuffs and products.

It happens that this year the Medical Research Council are able to draw attention to several therapeutic innovations, certain of which are based on work done in their own laboratories or elsewhere under a grant from the funds at their disposal. The great service done by the Council in fostering medical progress is bearing fruit not only in the opening up of new avenues of approach, but in making available for general use the results of scientific investigation at the earliest possible moment, and in the critical examination of new methods of diagnosis and treatment. We summarise below some of their comments on methods of treatment.

COMMENTS ON INNOVATIONS IN TREATMENT.

Pernicious Anæmia.

Referring to the treatment of pernicious anæmia by the administration of liver, the Council note that Minot and Murphy made this discovery by directly applying in hospital practice the results of experiments made with dogs which Whipple and Robscheit-Robbins, of Rochester, N.Y., had just published. Here again, as in so many other instances, the experimental method has brought a practical advance where observational study through all the years had brought none. Here, too, is a fresh instance of service being given to mankind for which the dog was found to be especially fitted.

The coöperation of manufacturing firms was enlisted by the Council as soon as it was established that the unknown factor which effects the cure can be extracted on a commercial scale, and a simplification of the process used in America was worked out

[1] London: H.M. Stationery Office. 1929. Pp. 165. 3*s*.

at the Council's laboratories. As a result extracts of liver of proved potency are not on the market for patients who cannot tolerate a large daily consumption of uncooked liver as such.

Artificial Light.

Medical treatment by artificial ultra-violet light (as distinguished from sunlight) has lately come widely into use in this country with a rapidity not hitherto common even for the best attested therapeutic novelties. Great sums of private and public money are being expended upon it and large new commercial and professional interests are involved. The Council point out that some part of this new use of light has an indisputable scientific basis, but that prolonged researches give no scientific reason to suppose that the supply of vitamin D to the body for the treatment of rickets, or any other purpose, is better effected by ultra-violet rays falling on the skin than by the direct provision of the necessary food values. The use of artificial light to supply only what the right food can give is merely wasteful. It commonly costs three or four shillings to give by light an effective supply of vitamin D that would cost less than a penny if given by the mouth in the form of cod-liver oil or otherwise.

In order to ascertain whether ultra-violet light had any general beneficial effects, two series of controlled experiments were conducted on subnormal infants and on healthy school-children respectively by Dr. Helen Mackay and Dr. Dora Colebrook. In the first series (who were given cod-liver oil to eliminate the purely nutritive factor) no evidence could be found of any gain in weight, of lessened anæmia, or of better resistance to infective illnesses in the treated group as compared with a similar group of untreated children. The "control" group showed indeed rather fewer respiratory infections. In the second series, when conditions between the children with and without the treatment were equalised, the results of the light were wholly negative. It gave no gain in weight, height, or observed mentality or "spirits," and the incidence of minor ailments such as colds was actually rather higher among those receiving the light. The Council are aware of no properly controlled experiments which have been made elsewhere to set against these two series.

The only medical uses of "light" radiations, other than the supply of vitamin D, which have already a basis in physiology depend upon their power of exciting a local inflammatory reaction in the skin, on which power depends Finsen's method of treating lupus. Independently of this, work done in recent years for the Council has shown that light, when it has produced a much weaker inflammatory reaction of a larger area of the skin, indicated by an after-flush, does cause an increase in the power of the blood corpuscles, as tested in shed blood, to dispose of bacteria. But this increased bactericidal power of the blood, as shown in the laboratory, has not yet been correlated with any permanent effects of value in the body, and is quickly followed by a decrease of bactericidal power. Moreover exactly the same effects for good or evil follow inflammation of the skin blood-vessels inflicted by heat or by other irritants than light. There is no present reason to know that artificial light can do more in this way than a mustard plaster, which is indefinitely cheaper.

Dr. Duke-Elder, working at the Royal London Ophthalmic Hospital, has found, like some earlier observers, that direct "local phototherapy" notably hastens the healing of corneal ulcers. There is no equivalent evidence of successful local treatment of skin ulcers.[2] The results of a clinical inquiry recently organised by the British Medical Association on the treatment of varicose ulcers appear to put radiation high in the scale of effectiveness, but evidence is lacking that the high rate of recovery was due to the irradiation and not to the rest and bandaging which, at least in many cases, were concurrently applied.

The Light Committee of the Council have found no reason for weakened confidence in the claims made by a number of distinguished clinical observers for the value of carefully regulated exposure of patients to natural sunlight, especially in such conditions as surgical tuberculosis. However, it cannot be taken as established by scientific evidence that the sole, or even the principal, factor in the benefits obtained by such treatment is the relatively small ultra-violet component of natural radiation from the sun, or that similar benefits can be expected from treatment indoors with ultra-violet rays. In the absence of this evidence it seems fair to suspect that in much of the present advocacy of light treatment the results post hoc are accepted as propter hoc, and beyond that common fallacy there lie all the possibilities of faith-healing and suggestion, as well as those of simultaneous but unnoticed changes in the personal hygiene of those treated. It would seem to be the duty of those who take the responsibility of prescribing light treatment, not only to secure that its known dangers shall be avoided, but also to find and announce evidence of its benefits that do not come only from strong commercial advocacy on the one hand and popular credulity on the other. It would seem also to be the special duty of hospitals and school or other clinics expending large sums of public money upon artificial light to use part of the expenditure to demonstrate by properly controlled trials their justification for spending more.

[2] THE LANCET, 1928, i., 904.

Radium for Cancer.

In a brief review of the progress made during the period of about seven years since the Council was entrusted with 2·5 g. of radium by the Government the outlook has been transformed. In place of random empiricism definite technical methods have now been worked out for the treatment of cancer by radium for almost every region of the body except the stomach.

Modes of application have been devised and improved; problems of dosage in terms of mass of radium, its position, and time of exposure, have been successively brought nearer final solution. The rates of progress have been very widely different at the different hospital centres of work. But the Radiology Committee report that more recently effective effort is being made at "practically every centre," and this is taken as showing that there is now a widening circle of real interest in radium therapy among surgeons. This interest is coupled with the growing conviction that the full value of radium treatment "can only be discovered by exploring all the technical possibilities of radio-surgical access and of variations in dosage." It is already possible to say that any woman suffering from early cancer of the neck of the womb can have the disease locally removed by a course of radium treatment as surely as by the knife, and of course with less suffering and risk. Radium has already proved to be the best means of treating "inoperable" cancer of the mouth or tongue. Its use gives a prospect of cure certainly in excess of that offered by surgical means. In the "operable" cases it seems that it will soon replace excision, for it removes the growth locally without mutilation and with less scarring, and gives a good functional result. Even if the growth should have spread to the glands there is now a good prospect of radio-surgical methods eradicating the disease. Similar confidence is rapidly gaining ground in respect of cancer in other positions—for instance, in the breast in women and in the rectum in men. There is reason, moreover, to feel sure that this progress is only the beginning of an accelerating advance. The stage has been reached when the progress now securely made is undoubtedly stimulating interest and effort in a widening circle, and this will allow the best conditions for more rapid advance on an extended front.

As radium treatment has won its way from inoperable cases to the operable and earlier cases its successes have multiplied and the growth of faith in it has been both justified and accelerated.

If the advances in research work on its clinical side have been tardy here as compared with those over the same period in other countries such as Sweden or France, the reason may lie in the fact that abroad the work has been done at centres where the whole organisation on both its laboratory and its clinical sides has been so arranged as to keep progress by systematised and controlled trials as the prime object in view. For Great Britain the centres have been necessarily arranged chiefly within large voluntary hospitals, where skilled clinicians and pathologists are available together with organised accommodation for patients. The Council had little alternative to this without an expenditure upon a scale for which they

were not even approximately equipped. The great general hospitals, however, do not always offer in their traditions and in their arrangements, personal or material, the best conditions for systematic and rapid advance by research of a clinical kind. In individual hands and at some centres brilliant results have been achieved in recent months.

The public and the profession alike can now perceive that the stage has been fully reached when radium treatment must be put within the reach of all whose lives depend upon it. There is at present a wholly inadequate supply of radium in the country as well as a corresponding shortage of really trained operators and of available hospital beds. But since it will be long before finality in technique is reached, every treatment centre must be a research centre, and vice versa, and therefore in any sound national scheme of treatment most of the existing centres should be retained and expanded, and others established should be closely affiliated to the present centres.

Nephritis.

Prof. S. J. Cowell, then working under Prof. E. Mellanby at Sheffield, continued his researches during the year on the relation of diet to nephritis. He has found that vegetables, and especially summer-grown green vegetables, have a powerful protective influence against inflammatory changes in the kidneys and thereby prevent a high non-protein nitrogen accumulation in the blood. Experiments are being made to determine the exact nature of the protecting agent. Milk or cereal foods have no protecting action.

The work of Dr. A. A. Osman and Dr. H. G. Close at Guy's Hospital on the treatment of nephritis by alkalies has been maintained, and it is believed that in suitable cases this gives a much higher percentage of successful results than any other single form of treatment. Further evidence of the efficacy of alkalies in the treatment of anuria has been obtained, and some light has been thrown on the mode of action of alkalies in causing diuresis. The instability of the acid-base balance is found to be of importance in the causation of acute nephritis. Further experimental evidence has also been obtained that alkalies prevent scarlatinal nephritis.

Dental Disease.

Correlation of animal experiments with findings by Mrs. M. Mellanby goes far to suggest that the fundamental cause of the prevalence of dental caries is a defect of nutrition, and that it may be possible by dietetic measures to check the incidence of dental disease, even in the cases of defective original structure. With Dr. Lee Pattison Mrs. Mellanby has tested the effect of irradiated ergosterol on the initiation and spread of caries in children.

An important investigation has been begun at Birmingham by Mr. A. Deverall and Miss E. Brinton, where children in three institutions are receiving special additions to their ordinary diet with a view to determining the influence of these on the development of teeth and liability to caries. Miss Brinton has been responsible for the distribution of the special articles of diet, for noting any cases where owing to sickness or other cause the diet has been suspended, and for recording the family and personal history of each child, the physical condition (including the transference of notes from medical officers' records), and any personal idiosyncrasies.

Diabetes.

At King's College Hospital, London, Dr. R. D. Lawrence has discovered from recent experimental work that the usually accepted quantitative relationship between insulin and glucose does not exist. The normal ratio of dosage of insulin to carbohydrate used up is found not to hold beyond a certain point. Beyond this, relatively small increments of insulin can enable the body to dispose of increasingly large amounts of carbohydrate. With Dr. Olive Buckley he has investigated the factors, such as septic infections and toxins, which antagonise insulin action, and Dr. Buckley is investigating the eosinophilia which seems to be produced in many diabetics by the continuous injection of insulin. Dr. R. A. McCance has almost completed an analysis of carbohydrate foods which shows that the available carbohydrate of fruits and vegetables is less than has been supposed.

A request was received by the Council for the trial of a proprietary preparation named "Glukhorment." This was alleged to be a preparation from the pancreas containing a natural anti-diabetic principle which, unlike insulin, was effective if given by the mouth. Its use had been supported by Prof. von Noorden, of Frankfurt. Chemical examination by Dr. H. H. Dale and Dr. H. W. Dudley showed that "Glukhorment" contained enough of a substance indistinguishable from "Synthalin" to account for its recorded clinical effects. This finding has been confirmed by workers in Czecho-Slovakia and in Germany and by a clinical trial made by Dr. R. D. Lawrence.

Tuberculosis.

Dr. A. Stanley Griffith, working at the Field Laboratories, Cambridge, has given much of the past year to studies of the immunising value of the B.C.G. vaccine of Calmette and Guérin.

His work has not confirmed the conclusions that the ingestion or inoculation of B.C.G. can give complete protection in monkeys against an infection with virulent tubercle bacilli. With one exception all the vaccinated monkeys became infected and developed progressive tuberculosis. On the other hand, an absolute immunity has apparently been produced in a calf by intravenous inoculation of B.C.G. Experiments are now being made, with Prof. J. B. Buxton, to find the relative values of different methods of giving the vaccine, the most effective dosage, and the duration of the resulting immunity. The experiments completed show that immunity can be produced by intravenous, subcutaneous, or oral administration. Two calves fed by the last method have resisted completely the intravenous inoculation of 1 mg. of virulent bovine bacilli, which would have killed them without it in less than 20 days.

Dr. R. L. Vollum has continued his work on experimental tuberculosis with Prof. G. Dreyer at Oxford. This has been chiefly concerned with vaccination by different methods and after different cultural conditions of growth of the bacilli, followed by estimation of the resulting immunity.

Prof. C. H. Browning has tried to repeat observations by Danish workers on the treatment of tuberculosis by means of injections of metallic salts. Long series of injections of aluminium and manganese chloride were given with a wide range of dosage. So far little influence from the treatment has been observed. In tests with Rupell's serum in tuberculous mice no definite differences could be established between treated animals and untreated controls as regards the character and extent of the lesions or the number of tubercle bacilli present.

Puerperal Fever.

In the attempt to find prophylactic measures against puerperal fever the Council have promoted an extension on a large scale of the investigation Dr. H. Burt-White made in applying the Dick test to women before labour.

It had been shown by Dr. G. H. Eagles and others that a toxin similar to that which reacts in the Dick test for scarlet fever is found in many non-scarlatinal strains, including streptococci from puerperal fever. Dr. Burt-White has found that in a hundred prospective mothers admitted to St. Bartholomew's Hospital and to the City of London Maternity Hospital there was a close correlation between a Dick-positive result and subsequent puerperal sepsis. The correlation suggested so strongly the possibility and wisdom of rendering Dick-positive subjects immune to puerperal fever before labour that arrangements have been made for a thousand cases to be investigated by Dr. B. Jervis at the City of London Lying-in Hospital and Dr. G. Morgan at Queen Charlotte's Hospital, under the supervision of Dr. Burt-White and Dr. L. Colebrook. It is anticipated that a means of prophylaxis may be made available to antenatal cases who are shown by the Dick test to be susceptible to puerperal fever.

In the inoculation department at St. Mary's Hospital, London, Dr. Leonard Colebrook has completed one phase of his investigation of arsenical compounds in relation to the chemotherapy of streptococcus infec-

tions. It remains now to ascertain, by careful clinical trial, how much the streptocidal potency acquired by a patient's blood under the influence of these compounds will contribute towards the prevention and cure of streptococcus infections. These clinical trials have been begun and experimental work is also in progress. The drug used in these trials is a methylene bisulphite compound derived from salvarsan.

Canine Distemper.

Dr. P. P. Laidlaw and Mr. G. W. Dunkin have continued their work to a point when the knowledge acquired is capable of being usefully applied in practice to rendering dogs resistant to infection by distemper. In trials of the method upon over 1000 dogs kept under ordinary conditions, wherever a clear comparison has been possible between inoculated and uninoculated dogs the results have been strikingly successful, and evidence is lacking only as to the duration of the immunity conferred.

At the Tiverton Hunt 62 hounds were inoculated. None had distemper. The disease broke out among the older hounds in the same kennels in December, 1927, but no vaccinated animals took the infection. Four vaccinated animals were sent to a neighbouring kennel where distemper was present, but remained well.

In the Dulverton pack 5 out of 16 young hounds were inoculated, were exposed to infection, but remained well. Of the other 11, 9 took the disease and 3 died. Of hounds belonging to the Puckeridge pack 24 were inoculated. They were exposed to distemper and one contracted a mild form of the disease. Among the uninoculated hounds in the same kennels 70 took distemper and 22 died. In the Warwickshire pack 44 vaccinated hounds were exposed to infection without any taking the disease; 91 unvaccinated hounds kept together with these took distemper, 49 dying.

Apart from foxhounds, about 300 dogs of a variety of breeds have been vaccinated; none has been reported as contracting distemper.

The present method of immunisation is subject to some disadvantages, both as regards manufacture and administration. Further research, for a limited period, is therefore contemplated with a view to possible improvement in these respects. In the meantime, however, it is hoped that the benefits of the work already done will shortly be brought to the dog-owning public in general, and the Council are glad to learn that a commercial laboratory is now actively working towards large-scale production of the vaccine.

Sundry Other Disorders.

Gastro-duodenal Ulceration.—Further work on the intensive alkaline treatment of this condition has convinced Prof. H. MacLean and his colleagues at St. Thomas's Hospital Medical Unit that the method will cure the ordinary case of ulceration, and that surgical interference is entirely unnecessary in uncomplicated ulcers. Patients with adhesions and other complications may fail to respond, but evidence has been obtained which suggests that even cases with adhesions to sundry organs may do quite well. Although over 100 patients were treated during the last year only two required operation; in both cases extensive adhesions were found. The use of sufficient alkali, on the lines described in the published papers, has given excellent results and has enabled most of the patients to continue at work without the usual severe recurrence of symptoms.

Acute Intestinal Obstruction and Peritonitis.—In the Surgical Unit of St. Thomas's Hospital Mr. B. W. Williams has continued work on the clinical investigation of the use of antigas-gangrene sera in these cases with special reference to the efficiency of concentrated globulins. The concentrated serum has been found apparently efficient in counteracting toxæmia in 15 cases, doses of 20 c.cm. being apparently equal to doses of 100 c.cm. of the unconcentrated serum.

Trypanosome Infections.—The trial in experimental trypanosome infections of chemo-therapeutic agents belonging to the amino-styryl-quinoline group has been continued by Prof. C. H. Browning and Dr. R. Gulbransen. It is hoped that one of these may soon be available for testing in natural infections of larger animals. The problem of the treatment of relapses in trypanosome infections has been pursued further in the light of observations that killed parasites do not by themselves give rise to an effective immunity reaction.

At Cambridge Miss M. Vincent and Dr. P. Tate, under the direction of Dr. D. Keilin, are testing the antimalarial effects of various synthetic compounds upon the malarian parasite of canaries.

Oxygen Want.—At Leeds Dr. H. W. Davies, using a simplified form of the Davies-Gilchrist oxygen administration apparatus, has made experiments to determine the effects of subcutaneous and intraperitoneal injections of oxygen upon the oxygen saturation of the arterial blood in conditions of oxygen want. No increase of oxygen saturation could be found, and it is inferred that injection of oxygen cannot relieve oxygen want in human patients.

Graves's Disease.—The relation of Graves's disease to iodine metabolism has been studied by Dr. G. S. Williamson and Dr. I. H. Pearse and colloid secretion has been shown not to be responsible for the toxic factor in this disturbance. Moreover, the danger of thyroxin and iodine therapy in the treatment of simple goitre has become more apparent by studies which have shown that lymphogenic secretion in the thyroid can be stimulated, and toxicity in the gland aggravated or induced by iodine, thyroxin, or thyroid-gland treatment. In individuals of hypothyroid disposition the danger of inducing a permanent lymphocythæmia by these therapeutic measures has become apparent.

Cardiovascular Diseases. — At Manchester Dr. J. Crighton Bramwell and Dr. R. Ellis are studying after-histories of patients suffering from different types of cardio-vascular disease. One group, for instance, consists of 27 cases of auricular fibrillation treated with quinidine for from two to five years.

Amœbiasis.—With Dr. P. P. Laidlaw and Miss A. Bishop, Mr. C. Dobell has maintained the studies already reported upon the value and uses of emetine for destroying the amœba in the human body. Under defined experimental conditions they find that as little as one part of this alkaloid in five million parts of culture medium will kill the amœbæ in vitro. A much improved method has been devised for testing the toxicity of chemical agents upon cultures of the amœbæ.

Epilepsy.—The previous findings of Dr. W. R. Brain, Dr. H. D. Kay, and Dr. S. H. G. Robinson, in the Medical Unit of the London Hospital, that alterations in the level of the blood cholesterol are associated with the fits in epilepitc patients have been confirmed. The oral administration of cholesterol to epileptics has been tried and found to have no therapeutic value, but the evidence that it is absorbed by this route is unconvincing.

Familial icterus neonatorum has been investigated and treated by Dr. A. C. Hampson at Guy's Hospital. Up to the present time 14 cases have been treated with serum—all successfully.

Enteric Carriers.—The investigation under Prof. R. Muir and Prof. C. H. Browning has been continued by Dr. K. Guthrie. Of two intestinal excreters operated on by Mr. Farquhar Macrae the one infected with *B. typhosus* has now consistently failed to show the organism in weekly examinations over a period of five years; the other, infected with *B. paratyphosus* B, has similarly given negative results over a period of three years. Cultures made from the duodenal contents in both cases failed to yield any growth of the specific organisms. These results provide confirmation of the efficacy of operation on the gall-bladder, usually cholecystectomy, in curing the carrier condition in a large proportion of cases.

CANCER AND TUBERCULOSIS:

THE SUPPOSED ANTAGONISM.

THE publication by Prof. Raymond Pearl of a paper entitled Cancer and Tuberculosis in the *American Journal of Hygiene* for January raises once more the question of an antagonism between these diseases. Although a great deal has been written about it, no quite conclusive answer has been given to what seems a simple statistical question. Prof. Pearl has tackled the problem in two ways. An analysis of the admirable autopsy records of the Johns Hopkins Hospital forms the groundwork of his paper, while subsidiary evidence from vital statistical data is also brought forward.

A series of 816 records of persons in whom some form of malignancy was discovered at autopsy was compared with an equally large sample in which there were no signs of new growth. The control group was selected in such a way that each member of the series agreed with one of the malignant series in respect of age, sex, colour and, as far as possible, date of death. From these data the incidence of active and healed tuberculous lesions in the two groups was calculated, and the conclusion is reached that there is a definite incompatibility between malignant disease and tuberculosis, such that the two very rarely occur together in florid activity in the same person. Taking the whole series, only 6·6 per cent. of those with malignant growths showed signs of active tuberculosis, whereas in the controls active lesions were found in 16·3 per cent. This difference between the two groups was found to apply equally when each age, sex, and racial group was subjected to separate analysis. Healed tuberculous lesions, on the other hand, were no less frequent in the malignant than in the control groups.

The problem was then approached from the opposite point of view, and the incidence of malignancy in a series of persons with tuberculosis in any degree of activity was compared with its incidence in a control series either without tuberculosis or with only old healed lesions. Among the actively tuberculous the incidence (28 per cent.) was found to be approximately only half as great as in the controls (53 per cent.). In making the comparison any case with tuberculous lesions which showed even the smallest evidence of activity was relegated to the group "active tuberculosis." This procedure would tend to obscure the inhibitory effect (if any) of active tuberculosis on the development of new growth, and if a series of post-mortem cases in which there was a great deal of active tuberculosis (e.g., acute ulcerative tuberculosis, tuberculous meningitis, vertebral caries) is compared with an adequate control series the difference in incidence should be relatively greater. This proved to be so, for of 886 persons with much active tuberculosis only 11 (1·2 per cent.) showed signs of malignant tumour, whereas in 886 persons of the same age, sex, and racial constitution 82 cases (9·3 per cent.) of malignancy were found. This general result again holds good for each separate age, sex, and colour group.

Malignancy in the control group was thus nearly eight times as frequent as in the series with a great deal of active tuberculosis, whereas when tuberculosis of any degree of activity was compared with controls the incidence in the latter was only twice as frequent. This suggests that there is a simple quantitative relation—that in the inhibition of malignancy it is not only the *presence* but also the *amount* of active tuberculosis which is important, and that the antagonism between the two diseases disappears when the tuberculous process heals or retrogresses.

With such clear autopsy results, it might be anticipated that official mortality statistics would provide valuable confirmatory evidence, and in a sense this is true. Prof. Pearl points, for example, to the higher tuberculosis and the lower cancer mortality in the male sex, the different ages of maximal incidence of the two diseases—tuberculosis being chiefly a disease of early, cancer predominantly one of later life—and the higher tuberculosis and lower cancer mortality in coloured compared with white races. The recorded secular trends and the incidence of the two diseases in the various organs of the body are not inconsistent with the view that antagonism does exist, but are insufficient in themselves to demonstrate causal connexion. More refined analysis of available mortality records only serves to emphasise the need for caution in the interpretation of statistical data. In a series of 22 States of U.S.A. the correlation between mortality from pulmonary tuberculosis at one decade of age in 1910 and that of cancer at the next higher decade in 1920 was determined. Contrary at first sight to what would be expected from the results of autopsy analysis, the correlations are all substantial in magnitude but *positive* in sign, indicating higher cancer mortality in areas with high tuberculosis rates. If mortality is a reasonable index of morbidity incidence this might be interpreted in such a manner that autopsy and official mortality returns would appear to be hopelessly at variance. But Prof. Pearl, rightly more impressed by the autopsy findings, offers an alternative explanation, equally plausible and reconciling otherwise discrepant results. Autopsy data indicate that active tuberculosis alone protects the organism against cancer. If, under prevailing environmental conditions, only a limited number of persons will ever develop florid active tuberculosis, and if the mortality from this cause is very high at any given age, the number left to develop active tuberculosis at later ages will be smaller than if the death-rate previously had been low. Consequently, if antagonism between the two diseases does exist, relatively more persons from a given age-group will reach a later age lacking the protection from cancer afforded by active tuberculosis, and a high cancer mortality combined with high antecedent tuberculosis mortality would result in such a community. Prof. Pearl realises that this is mere hypothesis, and conservatively concludes that official vital statistics present nothing contradictory to the conclusions reached from the more exact autopsy material.

This is probably the most thorough investigation of the problem which has yet been made. It is being followed up by experimental and clinical work, the results of which will be awaited with great interest.

DEATHS IN LONDON STREETS.—Deaths in street accidents in the London area during 1928 numbered 1237, being 181 more than in 1927. In the last quarter of the year the total was 365, or four deaths a day. In 1920 the number of persons killed was 638, in 1925 840, and in 1927 1056. Private motor-cars caused 120 deaths and 11,623 accidents to persons and property, trade and commercial mechanically propelled vehicles 101 deaths and 7318 accidents to persons and property. Of the 365 persons killed, 258 were pedestrians, of whom 126 are recorded to have "crossed the road without due care." The total of drivers and occupants of vehicles who lost lives was 22.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—The Fellowship announces that there will be no special courses until after Easter. The first course in April will begin on the 11th and will be a practitioner's course in medicine and surgery at the London Temperance Hospital, lasting two weeks, with daily sessions from 4·0 to 5·30 P.M. The London School of Tropical Medicine has arranged a series of eight clinical demonstrations to take place at 2 P.M. on Tuesdays and Thursdays, from April 9th to May 2nd. A course on treatment by electrotherapy will be given at the Royal Free Hospital on four successive Wednesdays at 5.15 P.M. from May 10th (entries limited to 16). Two courses will begin on April 15th, the first a course at the Royal Waterloo Hospital, in medicine, surgery, and gynæcology, occupying every afternoon, and some mornings, for three weeks, and the second, in neurology, at the West End Hospital for Nervous Diseases, every afternoon at 5 P.M., for four weeks (minimum entry 10). Syllabuses of all courses may be had from the secretary of the Fellowship at 1, Wimpole-street, London, W. 1.

Correspondence.

"Audi alteram partem."

CEREBRAL SURGERY.

To the Editor of THE LANCET.

SIR,—The leading article on cerebral surgery in your issue of Feb. 16th, inspired by Mr. Hugh Cairns's very interesting report on his experiences in Dr. Harvey Cushing's clinic in Boston, must have left a painful and misleading impression on the minds of your readers in regard to neurology in general and neurological surgery in particular as practised in Great Britain. It is my object, if possible, to remove this impression which, it is only fair to emphasise, is not confirmed by a careful perusal of Mr. Cairns's paper.

It is doubtful, for instance, if Mr. Cairns really intended the writer of your leading article to believe that the examination of the fundus oculi, the investigation of the visual fields, and X ray examinations are either "amongst the more recent advances in diagnostic methods" in cerebral tumours, or that they originated in America. Surely they have formed a part of the routine examination of every case in this country for many years past. Ventriculography, on the other hand, is still on its trial and its employment must always add to the sufferings, if not to the dangers, to which the patient is exposed. A false idea of its value may easily be conceived in the absence of adequate experience and skill in the interpretation of symptoms and physical signs. That this is sometimes the case is shown by a quotation from Mr. Cairns's report: "In 1925 Grant published a report of the pooled experiences of the American Society of Neuro-Surgeons. Ventriculography had been used in 392 cases and was held solely responsible for localisation of the tumours in 93 cases, or 30 per cent. of the verified tumours."

As a physician, it would be presumptuous for me to speak too positively, but I should be surprised if my surgical colleagues "read with special interest Mr. Cairns's account of the principles which underlie Cushing's surgical methods—namely, (1) avoiding injury to the brain, (2) hæmostasis, and (3) asepsis and closure of the wound." It would surprise me less if they dubbed such a statement a surgical platitude. But world-wide principles in surgical methods are not infallible, and we learn from Mr. Cairns that "one of the earliest and most frequent complications after operation is the formation of a blood clot between the dura and the overlying bone of the osteoplastic flap. The clot compresses the brain and may be fatal if not discovered quickly."

It has for long been obvious to British neurological surgeons and physicians that a low mortality-rate depends chiefly on two factors: (1) early diagnosis, and (2) the non-gliomatous nature of the tumour. In your leading article appears the remarkable statement: "A low operation mortality-rate justifies early cerebral exploration and so leads to the removal of tumours at an earlier stage of their development than has hitherto been possible"—a unique example of putting the cart before the horse. It is an early diagnosis which justifies early cerebral exploration, with removal of a tumour when it is removable, and so renders possible a low mortality-rate. Moreover, alleviation of suffering and disability, where radical cure is impossible owing to the gliomatous nature of the tumour, is more easily attainable when the diagnosis is made before headache, vomiting, and optic neuritis have become severe, and a high intracranial pressure has increased the dangers of operating. It is a pity that more attention is not drawn, either in Mr. Cairns's paper or in your leading article, to the absence or tardy development of headache and papilloedema in many cases of intracranial growth which are the most amenable to surgical intervention and which are not beyond the powers of neurologists to detect and locate.

My personal acquaintance, during the last 30 years, with the work of Sir Victor Horsley and his disciples prevents my subscribing to the statement that "for many years technique has lagged behind diagnosis in neurological surgery," and I am not satisfied that the results they have obtained have been inferior to those reported from the Boston clinic by Mr. Cairns. The latter's report naturally contains little indication of permanent results in relation to functional efficiency and the statistics he publishes in regard to operative mortality are of little importance for purposes of comparison, in view of the fact that they are based on a series of cases of which nearly 40 per cent. were of pituitary or acoustic nerve origin. It is not fair to Dr. Cushing, therefore, that the writer of your leading article should hail them in these words: "These remarkable figures, which it is safe to say have never been equalled elsewhere, will excite not only admiration but a demand to know how they are achieved."

May I submit very respectfully that surgical technique must always have an individual and personal flavour, and that two surgeons practising with the same principles but entirely different details of technique may attain equally successful results. Dr. Cushing's work has always commanded the deepest respect of his many friends and admirers in this country and he does not need to be told that every detail of his technique is studied with care and interest. While agreeing that "it is well at times to recognise that there are forms of mutual indebtedness between nations which excite no feelings but gratitude," I can hardly believe Dr. Cushing would express his belief in his own methods and his regard for his English colleagues in language such as this: "It is clearly to the patient's interest that Cushing's methods should be practised as widely as possible, though it must not be supposed that English neurology has nothing to contribute to neurological surgery"!

I am, Sir, yours faithfully,

Oxford, March 18th, 1929. E. FARQUHAR BUZZARD.

OPERATING FOR APPENDICITIS.

To the Editor of THE LANCET.

SIR,—Regarding an objection to the delayed system of treating certain cases of appendicitis—viz., that the patient having passed the crisis fails to submit himself for appendicectomy, for three years I have worked on the following plan. As soon as it is evident that resolution of the disease may be confidently expected the patient is handed two cards to sign. On each is printed:—

"I realise that I have just been tided over an attack of appendicitis. The surgeon considered that in my case it was safer to defer operation. I fully understand the danger of leaving the appendix, and I agree (1) to come into hospital on.....; (2) to report at the hospital immediately if I have any symptoms before that date

"Signed, ————."

Before this plan was adopted I found that more than 5 per cent. of the patients who had successfully undergone Ochsner's treatment failed to return. They were written to and a proportion replied with various excuses, the principal being that they had not fully understood the advice. Since the plan has been in operation, in only two instances has the patient neglected to keep the agreed appointment. Two cards are signed: one the patient takes away, the other is indexed and serves to remind the staff of the appointment, which, except in special cases, is made for a date two months after leaving. Experience shows that in the average case an interval of two months is necessary for the products of inflammation to resolve completely. In exceptional cases three months is necessary as Mr. Love emphasises.

I am, Sir, yours faithfully,

HAMILTON BAILEY.

Edgbaston, Birmingham, March 17th, 1929.

GAMMA RADIATION.

To the Editor of THE LANCET.

SIR,—The note by Mr. Wakeley and Dr. Colwell on the radium treatment of cancer of the rectum in your last issue conveys the impression that the treatment described by them is entitled to the heading "gamma radiation." The authors emphasise "gamma radiation" not only in the title of the note but in stating: "It is clear from the filtration that the neoplasms were subjected only to gamma radiation." After careful perusal of the article we think that the method described hardly comes under the heading of "gamma radiation." The tubes used contained 50 mg. of radium sulphate; the length of the tubes is not stated, but screened by 1 mm. of platinum and rubber tubing they will only give pure gamma irradiation if their linear intensity is about 1 mg. of radium per cm. length. In that case the containers would have to be about 50 cm. in length, an impossible proposition.

We presume that the length of the torpedo-shaped containers was commensurate with the length of the growth attacked, perhaps 4 or 5 cm. The linear intensity of such tubes screened as described is such that pure gamma radiation is out of the question, unless placed at a considerable distance (10 cm. or more) from the growth which is impossible when applied within the lumen of the rectum. Radium therapy as practised by Mr. Wakeley and Dr. Colwell has produced necrosis in a large number of cases, owing to a combination of beta and gamma radiation. This can be achieved much more rapidly and with less expense by diathermy.

At the present time, when much public attention is focused on the possibilities of radium treatment of cancer, it seems to us that the note by Mr. Wakeley and Dr. Colwell is calculated to mislead some workers in the field who may not be aware that gamma therapy acts by dissolution and absorption rather than by destruction through necrosis (beta radiation), which causes great suffering to the patient. Gamma irradiation given with efficiently screened tubes of suitable intensity over prolonged periods of time produces no ill-effects and does not lead to necrosis, although it is not claimed that it is always curative.

Clinical experience leads us to believe that the importance of adequate screening is not always sufficiently appreciated and further, we believe that heavier screenage than is usually employed with needles at the present time will result in improvement in clinical results, and this is our excuse for criticism on this occasion.

We are, Sir, yours faithfully,

C. GORDON-WATSON,
STANFORD CADE.

London, W., March 16th, 1929.

GLASS-WORKERS' CATARACT.

To the Editor of THE LANCET.

SIR,—Your annotation of March 9th (p. 513) gives an incorrect account of the discovery of glassworkers' cataract in this country. I was the first to describe the peculiar features of this disease in the *British Medical Journal* of Jan. 24th, 1903. It was my paper that directed Sir Thomas Legge's attention to the subject as he afterwards told me; and it was I who first showed the small Home Office committee consisting of Dr. G. J. Burch, Mr. Marcus Gunn, Mr. W. Anderson (all of whom are now dead), Mr. (now Sir) Herbert Parsons, and Dr. Legge the first 10 cases of the disease they had ever seen. These I demonstrated to them in the Sunderland Eye Infirmary. The circumstances were set out in a paper read before the Oxford Ophthalmological Congress in July, 1915, and published in *The Ophthalmoscope* for November, 1915.

I am, Sir, yours faithfully,

WM. ROBINSON.

Sunderland, March 10th, 1929.

THE INJECTION TREATMENT OF VARICOSE VEINS.

To the Editor of THE LANCET.

SIR,—If I write you again on the subject it is chiefly that I may make brief reference to the courteous letter of Sir Sidney Alexander, with whom I think I had some private correspondence on the subject a year or two ago, and who, as one of the earlier exponents of the injection method, and, so far as I know, one of the most temperate of its advocates, is entitled to have due weight given to the views he may express thereupon.

Sir Sidney quotes at some length from an appreciative letter, testifying to the great benefit derived by one of his patients from the injection treatment, after extensive operative treatment by excision and ligation had failed to cure. Though I might point out that the testimony of the patient seems to have been given too soon after the injection treatment (1926), and there is no later testimony as to the permanency of the benefit, I would not seek to labour unnecessarily this defect in the proof. Even accepting the case, however, at the value at which Sir Sidney assesses it, I might suggest that, if the injection treatment can ever be justified, probably this was the type of case that might most reasonably be submitted to it; a case, that is to say, where the extensive previous operations had presumably shut off most, if not all, of the avenues for systemic dissemination of clot. In other words, Sir Sidney carried out the injection treatment under conditions in which the risk of embolism had been very substantially lessened. If I were inclined to admit the justification of the injection method under any circumstances whatever, I should probably find the justification in such circumstances as were present in this case.

One further reference to Sir Sidney's letter. He points out that I seem to think "that a large number of cases of varicose veins do not require treatment." That is correct, but surely such a view is common to all. I might even assume that Sir Sidney shares this opinion. We may differ in view as to the relative proportion of cases that require treatment, but surely no one has reached the position yet where one might say, "Hello! Here is a varicose vein; let's inject it." Further, I must insist on the undesirability of meddling with the "odd superficial vein causing no trouble whatever, but perhaps showing as a bluish streak, &c." The type of vein to which I have referred is, in the great majority of cases, not a varicose vein at all; nor has it any very great tendency to become varicose. Such visible, but in no way disfiguring, superficial venules are to be seen in a very large proportion of women, and even in men, and they generally give no trouble—unless to the vanity of the flapper. It is surely not our duty to pander to this vanity.

May I take this further opportunity of restating the chief points in my case against the injection method? It seems necessary to get back to fundamentals—to general principles. In my official capacity I have the duty of teaching the student of surgery, and I am bound to teach him what I believe to be basic principles—principles, that is to say, which have a certain fixity or stability, though varying deductions may be made from them by different people. I endeavour to approach the subject of the injection method of treatment from this standpoint, and I would state my case against the injection method in the form of four questions.

First, is thrombosis, or is it not, a thing that the surgeon is justified in deliberately inducing under any circumstances?

Second, does the thrombus induced in the injection method differ, in any real essential that may be relied upon from the thrombus we so much dread as an accidental happening in surgery?

Third, are we able, as surgeons, to say with confidence that it will behave differently?

Fourth, can we confidently assure our patients that there is no risk attached to the injection method of treatment?

And, remember, it is the patient who has to take the risk.

I am bound to say that up to the present I have been unable to answer any of these questions except in the negative, and accordingly I am quite unable to commend to my students the injection method of treatment of varicose veins, nor would I like to appear, by my silence, to assent to the thesis put forward by the writer of the annotation that prompted my original letter—namely, that the case for the injection treatment is now proved beyond question.

I am, Sir, yours faithfully,

ARCHIBALD YOUNG.

The University, Glasgow, W., March 11th, 1929.

THE PREVENTION OF INFLUENZA.

To the Editor of THE LANCET.

SIR,—Regarding the value of quarantine regulations in the prevention of influenza (discussed in a leading article in your issue of March 2nd), may I state that during the pandemic of 1918 the late Dr. F. E. Rainsford, then medical superintendent of the Stewart Institutions for Imbeciles and the Hospital for the Insane, Palmerston House, Co. Dublin, called together the staffs of both institutions and suggested they should not go into the City or infected areas during their leave. He also prohibited all visiting, and every care was taken with admittance of food. The result was, his was the only institution in the United Kingdom and Ireland which had no case of influenza, owing to his continuous watchfulness night and day.

I am, Sir, yours faithfully,

E. A. RAINSFORD.

Kingstown, Co. Dublin, March 10th, 1929.

CHRONIC CARBON MONOXIDE POISONING.

To the Editor of THE LANCET.

SIR,—I am trespassing on your space in order to draw the attention of a wider audience to a series of troubles caused by fumes which have recently come under my notice.

In the first category, I have come across lately a number of cases showing headache, fatigue, dizziness, irritability, emotional disturbances, and gastric symptoms, which have been promptly relieved by a change of air, only to relapse when the patient has returned to her original surroundings. In one of these cases, at any rate, it has been found that there was a small leak of gas in the bedroom of the patient, and her symptoms, which had been previously regarded as neurotic, disappeared completely following the repair of this leak. In another case the patient always felt giddy after a bath; the bathroom was very small and the hot water was supplied by a geyser which was fitted with an effective vent-pipe. The room, however, was poorly ventilated and rapidly became full of steam. It was the patient's habit, contrary to instructions, to leave the geyser on during the time he had his bath, and there was ineffective combustion due to clogging of the burners. These symptoms also rapidly cleared up following attention to this point. In another group of cases I have had examples of men who spent a large part of their day in closed saloon cars fitted with an imperfect exhaust. These men have suffered from symptoms thought to be neurotic, but which have cleared up when attention has been drawn to this possible cause. Chronic carbon monoxide poisoning affects the highest centres first, producing fatigue, irritability, and emotional disturbances as the earliest symptoms.

I am mentioning these points because chronic carbon monoxide poisoning is not an uncommon event in my experience. The acute cases are readily recognised, but these chronic cases, in which the subject inspires small quantities of carbon monoxide gas over a long time, may easily escape notice or thought to be of a psychic origin. It has been pointed out by Glaister and Logan that an ordinary 20 h.p. motor-car will produce in five minutes sufficient gas in the exhaust to make the atmosphere of a small garage noxious, and the writer has personal experience of severe headache following whiffs of exhaust gas which are occasionally met with in London traffic blocks. It might be of interest to note that analysis of the air round Vauxhall and in Paris shows that a small percentage of carbon monoxide is occasionally present.

The treatment for the conditions is not by drugs except in a secondary capacity, but consists in replacing the amount of available oxygen which is lost to the body by a combination of hæmoglobin with carbon monoxide. This, of course, can be done either by a change of air immediately or by inhalation of oxygen and 5 per cent. carbon dioxide through a properly fitting inhaler. In the writer's experience, which is detailed at length in a recent paper on fume diseases to the Medico-Legal Society, this condition is commoner than is generally supposed.

I am, Sir, yours faithfully,

GERALD SLOT, M.D.

Harley-street, W., March 8th, 1929.

NOISE AND ANNOYANCE.

To the Editor of THE LANCET.

SIR,—I have read your article in THE LANCET of to-day's date with pleasure, but I would like to give you the true history of the campaign against noise so far as the British Medical Association is concerned. I was the first to bring the matter as a public health problem before the Public Health Committee of Edinburgh Town Council. The committee was quite in agreement with my view that noise should be treated as a nuisance within the meaning of the Public Health Act (the Scottish Act is the latest for 1897). I then brought the subject before the Division and Branch of the B.M.A. here, and they agreed upon the resolutions which were adopted at the Cardiff Annual Meeting. The Town Council of Edinburgh is now promoting a Provisional Order, and there is to be a clause in it dealing with noise. This will come before Parliament at an early date.

You will see from the above facts that I have played a rather important part in getting public opinion, and especially medical opinion, to bear on the question. I gladly acknowledge the part that Prof. Spooner and Dr. Dan McKenzie have played in the initial and present stages of the propaganda.

I am, Sir, yours faithfully,

Edinburgh, March 16th, 1929. T. G. NASMYTH.

ERRATUM.—In an article on the use of avertin for anæsthesia by Dr. J. Blomfield and Dr. F. E. Shipway, which appeared in our last issue, the word *omnopon* was printed in two places as omnoform.

LIVERPOOL FOOT HOSPITAL.—This institution was opened only at the end of October, but it has treated 1369 patients, and a third operating room is already needed. The work is restricted to the alleviation of minor foot troubles; patients who require surgical treatment are recommended for admission to a general hospital.

QUEEN CHARLOTTE'S MATERNITY HOSPITAL.—This hospital has decided to purchase a site of five acres on the Goldhawk-road, near Ravenscourt Park Station, in the borough of Hammersmith. Building will soon begin on the first section of what it is hoped will ultimately be the largest maternity hospital in the Empire. Mr. Edwin Stanley Hall, F.R.I.B.A., has been appointed architect, and the first section of the work to be carried out will be that of a separate isolation block, with research facilities for patients suffering from puerperal fever. Such cases will be received in large numbers, and laboratory research and the training of post-graduate students and midwives will be based upon the study of them.

Public Health Services.

INFLUENZA.

CLINICAL reports indicate that the epidemic has now passed its maximum in most districts of England and Wales. An increase in the number of cases is reported from Birmingham and Shrewsbury, and the incidence is still high round Norwood and Selhurst and on the Hampshire borders of Surrey. There is also considerable prevalence in Nottingham, Lincoln, Grimsby, Doncaster, Sheffield, Leeds, Bradford, and other West Riding towns, as well as in Norwich, Newmarket, Buckinghamshire, and South Wales. A definite decline is reported from Manchester, Liverpool, and other Lancashire towns, Newcastle, and South Shields, as well as in London, Reading, Portsmouth, and Southampton. The disease is mostly mild but a certain amount of pneumonia is reported from some of the larger towns, as well as from Radstock in Somerset. In Grimsby many cases are proving rapidly fatal from acute œdema of the lungs. On the continent the epidemic has apparently reached its maximum in Northern France and the Rhine area, while it is on the wane elsewhere.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED MARCH 9TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 289; scarlet fever, 2215; diphtheria, 1137; enteric fever, 28; pneumonia, 5818 (last week 5874); puerperal fever, 42; puerperal pyrexia, 131; cerebro-spinal fever, 15; acute poliomyelitis, 6; acute polio-encephalitis, 2; encephalitis lethargica, 28; dysentery, 8; ophthalmia neonatorum, 103. No case of cholera, plague, or typhus fever was notified during the week. It will be seen that the notifications of pneumonia have not quite reached the level of the previous week.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on March 12th–13th was as follows:—Small-pox, 88 under treatment, 9 under observation; scarlet fever, 1708; diphtheria, 1876; enteric fever, 8; measles, 81; whooping-cough, 1119; puerperal fever, 18 (plus 8 babies); encephalitis lethargica, 78; polio-myelitis, 7; "other diseases," 68. At St. Margaret's Hospital there were 11 babies (plus 6 mothers) with ophthalmia neonatorum.

The increase of 54 in the number of small-pox patients under treatment or observation in M.A.B. Hospitals is a corollary of the fact that cases of small-pox are being reported from many of the metropolitan boroughs—namely, in the week under review, from Bethnal Green, 1; Finsbury, 3; Islington, 1; Lambeth, 1; Poplar, 5; St. Pancras, 1; Southwark, 3; and Stepney, 3; while East Ham reported 2 and West Ham 43 cases.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 88 (1) from measles, 10 (3) from scarlet fever, 250 (74) from whooping-cough, 42 (5) from diphtheria, 65 (9) from diarrhœa and enteritis under two years, and 2127 (312) from influenza. The figures in parentheses are those for London itself.

The number of deaths from influenza during the previous eight weeks was 122, 179, 321, 652, 987, 1243, 1764, and 2183 respectively, the figures for London during the same weeks being 34, 39, 77, 198, 331, 393, 473, and 424. It will be seen that the peak has been passed, not only in London, but in the country as a whole. In the week under review deaths were, however, attributable to influenza in Birmingham, 266; Sheffield, 114; Leeds, 94; Stoke-on-Trent, 80; Bristol, 58; Manchester, 55; Bradford, 54; Leicester, 39; Oldham and Hull, each 36; Walsall, 35; Bolton and Middlesbrough, each 31; while 11 other towns reported between 20 and 30 fatal cases. Deaths from whooping-cough are still widely distributed, the highest figures coming from Manchester, 14; Bolton, 13.

The number of stillbirths registered during the week was 288 (corresponding to a rate of 38 per 1000 births), including 52 in London.

Death-rates from Influenza for the Last Six Weeks.

The course of the influenza epidemic in different parts of the country is indicated by a table which was printed in our issue of March 2nd (p. 471) and the figures of which are here brought up to date.

Week ended—	Aggregate.	North.	Midlands*	South*	Wales.	Greater London
Feb. 2nd, 1929..	1·73	2·14	0·48	2·56	0·53	1·89

*Excluding Greater London.

The Registrar-General also compiles the annual death-rates last week for the aggregate of great towns and for some of the largest of these, to illustrate the effect of the present epidemic. They are as follows: 107 great towns, 31·4; London, 28·9; Birmingham, 49·1; Liverpool, 20·4; Manchester, 28·7; Sheffield, 41·3; Leeds, 38·9; Bristol, 34·1; and West Ham, 26·5.

Obituary.

WALTER JAGGER, M.B., C.M. EDIN.

Dr. Jagger, who died at his home in Upper Berkeley-street on March 16th after a short illness, was well known to Edinburgh graduates in London, for he was for many years one of the secretaries of the Edinburgh University Club and an amusing speaker at the Club dinners in London. A native of Shrewsbury, he was educated there, going on to Edinburgh where he qualified in 1896. Joining the Royal Army Medical Corps, he served throughout the South African War, being awarded both Queen's and King's medals. On his return he went into general practice, after having first qualified himself by a series of appointments at Great Ormond-street, the Samaritan Hospital for Women, and the Lincoln County Hospital. During the late war he was on the staff of Princess Christian Hospital for Officers and the hospitals of the Royal Flying Corps in Eaton-square and Bryanston-square. He had a large practice in Mayfair, and his skill in midwifery was recognised by a command to assist at the birth of Princess Elizabeth. As a member of the Council of the Harveian Society he kept in touch with the medico-political problems of the day. Dr. Jagger married Muriel, daughter of Evelyn Rich, who survives him.

WILLIAM WRANGHAM, O.B.E., M.D., M.R.C.P. LOND.,

Dr. Wrangham, who died suddenly on March 6th, was one of the best known practitioners in Bradford. He came of a Lincolnshire family, members of which for several generations had been medical practitioners. His father was a doctor in Lincoln and his brother is Dr. J. M. Wrangham, of Ripponden. Born in 1871, he received his medical education at St. Bartholomew's Hospital and qualified in 1896. After spending nearly four years as a hospital resident he took his M.D. Lond. degree in 1900. Early in the century he settled in Bradford and was soon appointed assistant surgeon to the Royal Eye and Ear Hospital and assistant honorary physician to the Royal Infirmary, to which at the time of his death he was senior physician. He was also chief police surgeon and medical adviser to the Municipal Mental Deficiency Committee. When in 1915 the poor-law hospital was equipped as the Bradford War Hospital he was

appointed commanding officer with the rank of Lieut.-Colonel, and four years later was decorated for his services and received a personal letter from the General commanding the Northern Division congratulating him on the excellence of his administration of the hospital. When, in the following year, St. Luke's Hospital, Bradford, was established as the first municipal hospital in this country, Wrangham was appointed senior visiting physician. In 1921 he became a member of the Royal College of Physicians of London and relinquished general practice. From that time until his death he had had a large and steadily increasing consulting practice, and general practitioners found in him not only a very capable diagnostician, sound in prognosis and helpful in suggestions for treatment, but also a man of the highest probity, who was most honoured and respected by those who knew him best. Dr. Wrangham leaves a widow and two daughters.

ARNOLD WILLIAM MONTFORT AUDEN, M.B. EDIN.

Dr. Arnold Auden, who died on March 6th after a few days' illness, was the eldest son of the Rev. William Auden, vicar of Church Broughton, Derbyshire, and was born in 1863. He was educated at Shrewsbury School where he achieved considerable success as an athlete, winning amongst other events the school steeplechase and the quarter mile. In addition to being "gentleman of the runs," he was a sound football player and rowed in the school eight for two years. On going up to Clare College, Cambridge, he continued his rowing career, rowing in the Clare boat for the three years of his residence, and being boat captain in his last year. After taking the classical tripos in 1886, he took up the profession of teaching, but after some experience as a schoolmaster he decided to study medicine. Accordingly, he went up to Edinburgh University where he graduated as M.B., C.M. in 1895. After a short experience of practice at Shildon, County Durham, he settled down at Leigh, where he spent the rest of his professional life. A man of splendid physique, Dr. Auden devoted himself heart and soul to the demands of a wide and exacting practice, ever ready to help with generous charity the needy and impoverished of his neighbours. He took no part in public affairs, finding in his professional practice a sufficiently heavy call upon his energies and interests. He was unmarried.

ENCEPHALITIS LETHARGICA IN MANCHESTER.—The Manchester Corporation Public Health Committee has instructed the medical officer of health to ascertain whether the local authorities of South Lancashire would be willing to coöperate with Manchester in preparing a scheme for the treatment of persons suffering from encephalitis lethargica. The Ministry of Health has issued a circular urging all public health authorities to make special provision for such cases in their respective areas. The Manchester Committee had before them a report showing that while some cases are treated by the guardians in Swinton House and some in the ordinary ward of their institutions, there are other patients suffering from serious after-effects of the disease for whom additional accommodation is required.

DONATIONS AND BEQUESTS.—Dr. Oliviera Castro, of Portugal, has given £1000 to the Queen's Hospital for Children, Hackney-road, London, for the purpose of endowing a cot which will bear the following inscription: In memory of Eduardo A. Oliviera Castro, December, 1893, aged 14 years. This cot has been endowed in perpetuity by his father, Dr. Oliviera Castro, as a remembrance, and as a token of sympathy with suffering children amongst the English people, this most cultured and admirable nation. —Among other bequests, the late Mr. Thomas Arthur Springman, of Hampstead, left £5000 to the Royal Northern of Hospital Holloway-road, N.—Mr. Joseph John Johnstone, Craighead, Newport, Fife, left, among other bequests, £1000 each to the Dundee Royal Infirmary and the Royal Victoria Hospital, Dundee.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

LOCAL GOVERNMENT BILL.

ON Thursday, March 14th, the House of Lords considered the Local Government Bill on Report.

Administrative Schemes.

On clause 4 Lord COZENS-HARDY moved an amendment providing that the administration scheme should deal with the discharge of transferred functions and with any other similar functions now performed under the various Public Health Acts. The amendment was negatived on Lord ONSLOW'S representation that the present system should be trusted to carry out the functions satisfactorily. The portion of the amendment which might relate to the functions of hospitals, poor-law infirmaries, and cottage hospitals came up for discussion immediately after, upon an amendment moved by Lord HANWORTH to substitute for Clause 13 (Consultation with Bodies Representing Voluntary Hospitals) the following clause:—

"The Council of every county and county borough shall, after consultation with such body or persons within the county or county borough as represent the voluntary hospitals in the area, including representatives of the medical and surgical staffs of any voluntary hospitals in the area, make such arrangements as they think desirable for carrying into effect the functions transferred to them under this Part of this Act with respect to the provision of hospital accommodation and treatment."

"Accommodation" and "Treatment."

The omission of the original clause was agreed upon, and an interesting discussion ensued when Lord ONSLOW supported the amendment, which it will be seen provided for consultation with the representatives of the voluntary hospitals upon treatment as well as upon accommodation. Lord HANSWORTH pointed out that, if any question arose as to what body in a particular county be representative of the voluntary hospitals, the decision might be left to the Ministry of Health, a provision to that effect being inserted in the Bill.

Lord KNUTSFORD then spoke warmly on the question of treatment, drawing a vivid picture of the difference in the service at present provided at the large voluntary hospitals and at the poor-law institutions, while Lord BLEDISLOE gave further support to the amendment by pleading the cause of the cottage hospitals, pointing out in particular the work in treatment carried on by clinics in connexion with small village hospitals under the Education Act, 1921.

Lord DAWSON pointed out the large responsibility which would be undertaken by the new bodies when they entered the field of curative mdicine, as neither the county councils nor the medical men who advised them would have adequate experience of hospital administration for carrying on the new duties, and he suggested that it was the sense of the Committee that help should be brought to them not by compulsion but by conference with the voluntary hospitals and the staffs attached to them, and also with that part of the profession which had always dealt with curative medicine. "There should be," he said, "brought to the aid of these new hospitals the traditions, experience, and knowledge of the voluntary hospitals that had existed for generations, forming an organic nexus between the doctors and the hospital managers." The term "accommodation" to his mind meant fabric and arrangement of buildings, while the term "treatment" covered the purposes for which the structures were used. There was no suggestion that medical men or representatives of hospital managers were coming in at all times to interfere in the new hospitals, but it was meant that real conferences should take place to determine action not only in respect of the buildings to be put up but in respect of the purpose for which they were to be used. He was informed that the best way of providing this was to insert the words "and treatment," but he was wedded not to those words, but to the principle that those who had acquired experience through generations should be able to bring it to the aid of less experienced bodies and individuals. He drew an eloquent picture of the work of a general hospital in support of his contention, giving an illustration of the perils that might surround the ill-advised use of radium, and asked the House not to be satisfied with the mere question of accommodation and fabric, but to ensure that there should be conferences and consultation with the medical profession over the purposes for which the institutions were to be used. If Lord Onslow's clause met the situation why should not this fact be stated in plain English, while scepticism was caused by the fact that the medical profession had not been consulted in drawing up the poor-law part of the Bill. There had here been

no consultation with the heads of his profession. Surely, he said, it would have been natural to have called these heads together and to have said, "We are thinking of giving powers of general treatment to these new county hospitals; can you help us, can you give us advice, and draw up a scheme? We do not, of course, commit ourselves to accepting it." It was because there has been no proper consultation of that sort on the part of the Minister of Health that he was a little sceptical when he found that the Government's clause gave them nothing but a barren concession as to hospital accommodation and contained no words which said that the medical profession should be consulted as to the purpose for which that accommodation was used.

The New Clause.

The Earl of ONSLOW had on the paper the following proposed new clause:—

"The council of every county and county borough shall, before making provision for hospital accommodation in discharge of the functions transferred to them under this Part of this Act, consult with such committee or other body, if any, as they consider to represent both the governing bodies and the medical and surgical staffs of the voluntary hospitals providing services in or for the benefit of the county or county borough."

This clause he understood to meet Lord Dawson's views in regard to any question as to the body representing the voluntary hospitals in an area. He alluded to the number of local committees existing under the Voluntary Hospitals Commission, while the Hospital Association had also a network of committees which would be at the disposal of the local authority, these committees being admittedly formed of laymen. His lordship did not agree that it would be advisable to refer to the Minister of Health questions that might arise locally, as to whether the British Hospitals Association or the Voluntary Hospitals Commission should be selected, as he thought that matter could be left to local discretion. Referring to Lord Dawson's criticisms he considered that if the word "accommodation" was too narrow the same might be said of the word "treatment"—or they might both be termed too broad, for the inclusion of the word "treatment" would place the local authority under the obligation to consult a committee in respect of the medical treatment of patients.

Lord DAWSON proposed that if the word "treatment" could not be inserted the following words might be accepted—"hospital accommodation and the functions to which the accommodations shall be assigned," a suggestion that Lord Onslow said he was prepared to accept and one which fell in with the views of Lord Atkin.

The LORD CHANCELLOR pointed out the inadvisability of placing county councils under a statutory obligation to take advice from the voluntary hospital body with regard to treatment. Lord Dawson, he said, described this thing as the last that he desired, and their lordships would be wise not to insist on putting in words which apparently no one desired. He was sure that words could be devised to carry out Lord Dawson's contention, and he thought it possible to accept the Government clause with the understanding that before the third reading the Ministry of Health would make an effort, in discussion with Lord Dawson and those whom he invited to coöperate, to find what words would have the effect of bringing in the functions to which "accommodation" could be assigned, without implying interference with matters of detailed treatment. Lord Hanworth's clause being rejected by 52 to 42 votes, Lord ONSLOW moved the Government's new clause in the text given above.

An amendment by Lord DAWSON to add to the consultative bodies "the medical faculty of any university which serves the area, and the duly qualified medical practitioners in the area," was negatived.

Recovery of Expenses.

In a discussion upon the recovery of expenses Lord COZENS-HARDY moved the following new subsection:—

"Provided that any such council or authority may, by agreement with the governing body of any association or fund established for the purpose of providing benefits to members or other beneficiaries thereof, accept from the association or fund, in respect of the expenses incurred by the council or authority in the maintenance of any member or beneficiary of the association or fund, payment of such sums as may be provided by the agreement, in lieu of recovering the whole or any part of the said expenses from the member or beneficiary, or from any person legally to maintain him."

This was agreed to and the Report stage of the Bill was closed.

LOCAL GOVERNMENT (SCOTLAND) BILL.

On Tuesday, March 19th, in the House of Lords, the Earl of AIRLIE, Lord-in-Waiting, moved the second reading of the Local Government (Scotland) Bill. Earl BEAUCHAMP moved the rejection of the Bill. The motion for rejection was negatived by 66 votes to 22, and the Bill was read a second time.

HOUSE OF COMMONS.

WEDNESDAY, MARCH 13TH.

Sick Leave among Women Clerks.

Mr. KELLY asked the Minister of Pensions what was the average number of days of sick leave per head during each of the last three years in the case of women clerical officers, writing assistants, and members of the established typing grades, respectively, employed in his department; and what was the average number of days of sick leave per head in the case of each of the grades concerned taken on account of gastric or nervous trouble, respectively.—Major TRYON gave the information asked for in the first part of the question in the following table:—

—	Year ended Dec. 31st.		
	1926.	1927.	1928.
Clerical officers	9·3	12·7	12·1
Writing assistants	10·9	13·9	11·2
Typing grades	8·1	8·4	11·8

The figures exclude cases of officers whose sick absence amounted to 91 days and over.

The information asked for in the last part of the question was not readily available and could not be obtained without a detailed investigation.

Mr. KELLY asked the Home Secretary a similar question in regard to women clerical officers on the next day.—Sir WILLIAM JOYNSON-HICKS gave the information asked for in the first part of the question in the following table:—

—	1926.	1927.	1928.
Clerical officers	6·1*	6·7*	5·6
Writing assistants	6·2	6·0	4·4
Typing grades	10·9†	10·0	7·6

* Does not include one woman who had 284 days continuous sick leave in 1926 and 1927.

† Does not include one woman who had 105 days sick leave.

He was unable to give the information asked for in the last part of the question.

Mr. KELLY also asked the Under Secretary of State for India a similar question in regard to the women clerical officers in his department.—Earl WINTERTON replied: The following table gives the desired information:—

Year ended Jan. 31st.	Average number of days per head.								
	Sick leave.			Taken on account of gastric trouble.			Taken on account of nervous trouble.		
	Clerical officers.		E.T.G.	Clerical officers.		E.T.G.	Clerical officers.		E.T.G.
	M.	W.		M.	W.		M.	W.	
1927 ..	11·6	18·4	12·4	0·6	2·2	5·0	2·8	0·2	0·4
1928 ..	8·9	9·6	10·1	0·2	1·1	1·5	0·3	2·7	1·3
1929 ..	10·2	15·1	11·4	1·0	0·2	0·2	2·6	1·8	0·2

M., men; W., women. E.T.G., established typing grades.

Mr. KELLY also asked the Secretary for Mines a similar question with regard to the women clerical officers in his department.—Commodore KING gave the information asked for in the first part of the question in the following table:—

—	Year ended Jan. 31st.		
	1927.	1928.	1929.
Clerical officers—Men	6·43	9·77*	6·03
Clerical officers—Women ..	9·20	8·00	11·00†
Established typing grades ..	8·82	5·31	5·65

* Includes three cases of sick leave amounting to 64, 67, and 89 days respectively.

† Includes one case of sick leave amounting to 49 days.

The information asked for in the last part of the question could not be supplied as no detailed record was kept of the types of illness which accounted for the sick leave.

Chlorodyne as a Drug of Addiction.

Viscountess ASTOR asked the Home Secretary whether he was aware that fresh evidence as to the use of chlorodyne as a drug of addiction had come to light since the departmental committee on morphine and heroin addiction reported in 1926; whether, in view of the consequences of the abuse of this drug by persons being able to obtain unlimited quantities by purchase from several chemists at the same time and in the same town, he would bring the preparation within the scope of the Dangerous Drugs Acts; and, failing this action, whether he proposed at an early date to carry out Recommendation 103 (2), which would secure that no preparation could be sold under the name of chlorodyne which contained more than 0·1 per cent. of morphine.—Sir WILLIAM JOYNSON-HICKS replied: The recommendation of the Rolleston Committee has been under consideration, but legislation would be required in order to give effect to it. No opportunity for this has so far occurred, but the matter has not been lost sight of, and it is noted for consideration in connexion with the general question of the revision of the Pharmacy Acts which has been under investigation by a Departmental Committee. I may add that the evidence before the Home Office does not show that the abuse of chlorodyne has been increasing since the Rolleston Committee reported.

Medical Men and Lunacy Certification.

Dr. VERNON DAVIES asked the Minister of Health if his attention had been drawn to the fact that, owing to a recent High Court case, medical men would not run the risk of certifying insane people, and if he proposed to introduce legislation to deal with this situation, which was inimical to the best interests of the afflicted persons and the public.—Sir KINGSLEY WOOD (Parliamentary Secretary to the Ministry of Health) replied: My right hon. friend's attention has been drawn to this case. He hopes that any legislation which may be introduced to amend the Lunacy Laws will include a provision giving effect to the recommendation of this point of the Royal Commission on Lunacy and Mental Disorder.

Tenure of Office of Public Health Officers.

Dr. VERNON DAVIES asked the Minister of Health if his attention had been drawn to the decision of Mr. Justice McCardie in the King's Bench Division in Brown *v.* Dagenham Urban District Council, which affected the security of tenure of public officials by allowing their dismissal at any time at the pleasure of the body employing them, irrespective of any contract as to notice of termination of appointment; and what action he proposed to take to secure the position of officers appointed under the Public Health Acts in view of the state of the law revealed by this decision.—Sir KINGSLEY WOOD replied: My right hon. friend is aware of this case, and the matter is receiving his consideration.

THURSDAY, MARCH 14TH.

The London Lock Hospital.

Mr. PETHICK-LAWRENCE asked the Minister of Health whether he proposed to publish the report of the committee appointed to inquire into the London Lock Hospital.

Mr. ARTHUR GREENWOOD asked the Minister of Health whether, in view of the appeals being made on behalf of the London Lock Hospital and the public anxiety concerning it, he would, for the guidance of the public, publish the report of the committee of inquiry appointed early last year.—Mr. CHAMBERLAIN replied: I am glad to have this opportunity of explaining to the House that I have brought the recommendations of the Committee of Inquiry to the notice of the Board of the Hospital, and have received an assurance, which I accept, that they have already applied themselves to the task of carrying the greater part of the recommendations into practical effect. This task must involve a comprehensive review of the constitution and management of the hospital. A considerable time will therefore be required to complete it, and I do not think it would be in the public interest to publish details of arrangements at the hospital which are already under revision by the responsible governing body, if and so long as I remain satisfied that the extent of the changes made, and the rate of progress in making them, are reasonable.

Insurance Companies and Health Benefits.

Mr. COMPTON asked the Minister of Health whether there were any regulations under the national health insurance system whereby an insurance company with an approved society branch had authority to deduct the premiums due on the insurance policy from any benefits that might be payable.—Mr. CHAMBERLAIN replied: No, Sir. Any such compulsory deduction from the benefit due to an insured person under the National Health Insurance Act would be contrary to an express provision of the Act.

Health Insurance Benefit.

Mr. DAVID GRENFELL asked the Minister of Health if he would give the figures showing the number of weeks for which health insurance benefit had been paid from 1921 to the last available yearly record.—Mr. CHAMBERLAIN replied: Exact particulars are not available as to the number of weeks for which sickness benefit is paid under the National Health Insurance Act, and the following figures for England and Wales from 1921 to the latest year available, estimated from the amount paid each year for sickness and disablement benefits, can only be regarded as rough approximations.

Year 1921 .. 19 million weeks	Year 1925 .. 25 million weeks
,, 1922 .. 19½ ,, ,,	,, 1926 .. 28½ ,, ,,
,, 1923 .. 20½ ,, ,,	,, 1927 .. 30½ ,, ,,
,, 1924 .. 23½ ,, ,,	

Protection against Anthrax.

Mr. DAY asked the Minister of Health whether his attention had been drawn to an inquest held at Liverpool on March 6th on William Ronald Williamson, a tannery labourer, who died from anthrax; and, in view of the jury's recommendation in this case, if he would consider amending the present law so that in all places where anthrax was likely to be contracted arrangements would be made in order that all suspected cases could be examined and given serum if necessary at any hour of the day or night.—Sir WILLIAM JOYNSON-HICKS (Home Secretary) replied: I have received a report which shows that the death was not due to any lack of facilities for the appropriate treatment, but to the fact that the case was not suspected to be anthrax. A warning as to the dangers of anthrax and as to the necessity for immediate recourse to medical examination is required by Home Office regulation to be posted up in every works of this kind, and I am assured that supplies of the serum are available in all centres where the industries which are subject to this risk are carried on. The warning notice which I have mentioned also enumerates the places at which the serum can be obtained, so that even in the case of isolated factories a supply can always be made available in a few hours. The important thing is that any worker in the industry who is suffering from a boil or pimple or anything that may possibly be anthrax should obtain medical advice and treatment at once.

TUESDAY, MARCH 19TH.

Medical Examination of Emigrants.

Sir JOHN MARRIOTT asked the Secretary for Dominion Affairs how many of the families or individuals who, since January, 1928, had applied for assisted passages to Canada and Australia had failed to satisfy the medical or other requirements of the Dominions; and how many, having satisfied those requirements, had been refused an assisted passage by the Dominion authorities and the Imperial authorities, respectively.—Capt. MARGESSON (Lord of the Treasury) replied: The Dominion authorities are unable to furnish the information asked for in the first part of the question. As regards the second part, no applicants are refused assisted passages if they satisfy the medical tests, and also fulfil the other requirements of the Dominion Governments—that is to say, are going to approved employment and are likely to succeed in that employment.

BIRMINGHAM CONTRIBUTORY SCHEME.—The first complete year's working of this scheme has produced £157,000. In 1927 the Hospital Saturday Fund, which has been taken over as the industrial branch of the scheme, raised £66,000. The number of contributing firms has increased from 2637 to 4219, and the contributions in the factories and workshops have been standardised at 2*d.* per week in place of the varying amounts formerly paid. There are 330,000 contributory members.

ST. ANDREW'S HOSPITAL, DOLLIS HILL.—The annual report of this hospital, which is held in trust by the trustees of the Roman Catholic diocese of Westminster, and is specially intended to meet the needs of the professional and middle classes who cannot afford nursing-home costs, shows that the accommodation is being heavily taxed. Although there is no out-patients' department, more than 300 accidents and other urgent cases have had to be attended. A new pavilion with two wards and 24 beds and an operating theatre is being erected and the building of a nurses' home has been begun. The extensions will cost £30,000, of which only £7274 is as yet available.

Medical News.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At an ordinary meeting of the Council on March 14th Sir Berkeley Moynihan, the President, in the chair, the diploma of Fellow was conferred upon Ian Douglas Miller, Sydney Univ. and Guy's, who passed the examination in November last and has now complied with the by-laws. The diploma of Member was also conferred upon W. F. Skaife, Oxford and St. Bartholomew's Hospital.

Licences in Dental Surgery were conferred upon the following 31 candidates, who have passed the requisite examinations and have complied with the by-laws of the College:—

A. N. Bery, Univ. Coll.; T. Dagger, M.R.C.S., Liverpool; F. W. Entwistle, Manchester; S. P. Ellis, Guy's; F. G. Evans, Royal Dental; T. H. Felton, Manchester; L. W. G. Fisher, Guy's; H. L. Hale, Royal Dental; Alice M. I. Halsall, Royal Dental; C. Haskins, Bristol; J. E. M. Hennessey, London; O. B. Heywood, Royal Dental; O. M. H. Jones, Guy's; B. Joseph, Royal Dental; H. I. Leon, London; B. Lubner, London; C. D. Malone, Guy's; B. Margand, Univ. Coll.; K. S. Morris, Guy's; Irene Piperno, Royal Dental; R. V. Shepperd, King's Coll.; M. Smith, Manchester; F. H. B. Spence, Guy's; R. Symmons, Guy's; R. M. Tompkins, King's Coll.; T. E. K. Uren, Guy's; T. L. Vaisey, Guy's; B. R. Vincent, Univ. Coll.; W. N. L. Wade, King's Coll.; J. W. Woolley, Guy's; and J. L. Young, King's Coll.

The undermentioned diplomas were conferred (jointly with the Royal College of Physicians) upon the following candidates:—

Diploma in Tropical Medicine and Hygiene.—K. P. Anklesaria, F. C. K. Austin, T. C. Backhouse, R. Bandyopadhyay, S. Batchelor, P. S. Bell, D. D. Bhargava, W. K. Blackie, J. S. Brown, J. Bryant, J. A. Carman, Irene E. Chandler, A. D. Charters, L. S. Chatterji, N. Chilton, H. L. Chopra, J. C. Chukerbutti, N. E. Cook, M. Das, P. T. J. Doss, A. N. Duggal, D. P. Dutta, J. G. Green, H. E. Hargreaves, E. Haworth, R. S. F. Hennessey, H. Joomye, N. Kamchorn, Y. M. Khan, C. E. M. J. Libert, G. A. Messih, G. W. Milledge W. S. Nealor, S. L. Rikhye, S. F. Russell, E. H. Stahly, R. Stanford, Eileen M. Turner, G. G. Udeshi, Alice E. S. Wharton, J. B. A. Wigmore, A. J. W. Wilkins, Cicely D. Williams, and D. B. Wilson.

All of these candidates pursued a course of study at the London School of Hygiene and Tropical Medicine, except J. B. A. Wigmore.

Diploma in Ophthalmic Medicine and Surgery.—S. Annaswami, Y. P. Bedi, G. R. Bhatia, M. D. Bower, G. A. Bradshaw, C. S. Colvin, H. V. Coverdale, H. N. Dewan, Jean M. Dollar, J. B. Dhaubhoora, E. H. W. Elkington, W. D. Hamilton, M. Husnain, Audrey H. Henson, S. J. A. Laubscher, A. A. El. M. Magraby, Sigrid L. S. Pearson F. E. Preston, Gertrude E. Pugmire, B. W. Rycroft, A. E. M. Soliman, A. D. C. Stoute, Annie V. Taylor, Marjorie P. Taylor, and G. Vaishnavi.

UNIVERSITY OF LONDON.—At a meeting of the Senate on Feb. 20th it was resolved:—

(1) That the Department of Hygiene and Public Health at University College be closed on July 31st, and that the work for the Diploma in Public Health and for post-graduate and research students in hygiene hitherto carried on in that department, in conjunction with that in bacteriology carried on in the University College Hospital Medical School for candidates for the D.P.H., be transferred as from the same date to the London School of Hygiene and Tropical Medicine.

(2) That the teaching of Epidemiology and Vital Statistics for the D.P.H. be transferred to the London School of Hygiene and Tropical Medicine as from August 1st, 1929.

(3) That the teaching of, and direction of research in, Epidemiology and Vital Statistics, except for the D.P.H., at present undertaken by a Reader at University College, be continued in the Department of Applied Statistics and Eugenics at University College.

(4) That the Department of Municipal Engineering at University College be reorganised and as from August 1st be known as "The Department of Municipal Engineering and Hygiene."

It was also resolved that a degree of Ph.D. be instituted in non-clinical subjects for external students in the Faculty of Medicine, and that candidates for this degree be required to hold, in a branch of study akin to that in which they propose to proceed to the Ph.D. degree, the degree of M.B., B.S., or B.D.S., or B.Pharm., or B.Sc.

A course of lectures on mental deficiency, supplemented by a course of clinical instruction, will be held at the central buildings of the University from May 27th to June 1st, the arrangements being made by the Council of the Central Association for Mental Welfare in consultation with the University Extension Board. Besides the usual course it is proposed to hold a course in a second week (June 3rd to 8th), which will be open to those who have taken the ordinary course in this or some previous year, mainly for members of the School Medical Service, for the purpose of studying exceptional conditions closely allied to mental deficiency, with practical work including case conferences and discussions on cases presenting conduct difficulties. Full particulars may be had from Miss Evelyn Fox, c/o The University Extension Department, University of London, S.W. 7.

ROYAL DENTAL HOSPITAL OF LONDON: SCHOOL OF DENTAL SURGERY.—A course of post-graduate lectures will be given at this hospital at 6 P.M. on Wednesdays, April 10th and 24th, and the first three Wednesdays in May.

RADIOLOGICAL DIAGNOSIS OF RESPIRATORY DISEASE. A practical course on the Radiological Diagnosis of Pulmonary Tuberculosis and Disease of the Respiratory Tract will be held at Strasbourg from June 24th to 30th, under the auspices of the Faculté de Médecine and the Association Alsacienne et Lorraine contre la Tuberculose. The number of participants is limited to 15, and application may be made to Dr. E. Vaucher, 8, quai Finkwiller, Strasbourg.

ROYAL LONDON OPHTHALMIC HOSPITAL. — The Gifford Edmonds Prize in Ophthalmology has been awarded to Mr. V. M. Métivier, of the Ophthalmic Department of Edinburgh Royal Infirmary, for an essay on the Causation and Differential Diagnosis of Proptosis. The prize was founded by Miss Sophie Edmonds in memory of her brother, who fell at Magersfontein. It is valued at £100 and is awarded every second year.

SCHOLARSHIPS AND GRANTS IN AID OF RESEARCH.—The Council of the British Medical Association is prepared to receive applications for an Ernest Hart Memorial Scholarship of £200 per annum, and three Research Scholarships, each of £150 per annum. These are given to candidates qualified to undertake research in any subject relating to the causation, prevention, or treatment of disease. Each is tenable for one year, from Oct. 1st, and scholars may be reappointed for not more than two additional terms. A scholar is not necessarily required to devote the whole of his or her time to the work of research, but may hold a junior appointment at a university, medical school or hospital, provided its duties do not interfere with his work as a scholar. The Council is also prepared to receive applications for grants for the assistance of research into the causation, treatment, or prevention of disease. Preference will be given, other things being equal, to members of the medical profession and to applicants who propose to investigate problems directly related to practical medicine.

Applications for scholarships and grants must be made in prescribed form not later than May 25th. Particulars may be had from the Medical Secretary, at the Association's House, Tavistock-square, London, W.C. 1.

ROYAL SOCIETY OF MEDICINE.—The Society's house and library will be closed from Thursday, March 28th, to Tuesday, April 2nd, both days inclusive.

ROYAL NAVY MEDICAL CLUB.—The annual dinner of this club will be held at the Trocadero Restaurant, Piccadilly-circus, on Thursday, April 25th, at 7.30 for 8 P.M. Members who wish to be present are asked to inform the hon. secretary, at Queen Anne's Chambers, Tothill-street, London, S.W. 1, not later than April 17th.

LION HOSPITAL AID SOCIETY.—At the annual dinner of this society last week it was stated that last year £4500 was distributed to hospitals; when it was established 30 years ago the income of the first 12 months was £80. At the dinner £1600 was raised.

SEAMEN'S HOSPITAL SOCIETY. — At the annual court of governors last week Sir Arthur Clarke, the chairman, stated that the beds in the society's seven establishments now number 627. There was an adverse balance of £2000 on the year's working at the Queen Alexandra Memorial Hospital for Seamen at Marseilles, which became one of the society's hospitals at the beginning of 1928.

ST. MARK'S HOSPITAL.—The Lord Mayor of London, Sir Kynaston Studd, accompanied by the Lady Mayoress and the Sheriffs, visited the City-road on March 15th to attend the annual meeting of St. Mark's Hospital. He said that the number of patients admitted last year was 820, and that nearly 900 operations had been performed. The hospital had been enlarged, and the number of beds increased to 72, with a resulting increase of work in all departments, so that further extensions were already necessary, including additional accommodation for nurses, a second operating theatre, and an extension of the cancer research laboratories. These extensions would entail an expenditure of £30,000. Mr. J. P. Lockhart-Mummery spoke of the hospital's supply of radium. Hitherto this had been very meagre, but now, as the result of the generosity of one individual and the allocation of the King Edward's Hospital Fund, St. Mark's had possession for the time being of 250 mg.—enough to treat five patients every fortnight. It could, of course, utilise further supplies.

The Services.

ROYAL NAVAL RESERVE OF OFFICERS.

Surg. Sub-Lt. G. H. Bradshaw to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. F. A. H. Clarke, having attained the age for compulsory retirement, is placed on retd. pay.

Maj. and Bt. Lt.-Col. H. H. A. Emerson to be Lt.-Col., vice Lt.-Col. F. A. H. Clarke.

The undermentioned Lts. (on prob.) are confirmed in their rank: L. R. S. MacFarlane, W. F. Lane, C. L. Day, A. T. H. Marsden, G. L. Grieve, L. R. H. Keatinge, and W. D. Hughes.

Lt. S. M. Burrows is secd. for duty with the Sudan Def. Force.

Lt. J. M. Ryan is secd. under the provisions of Art. 205, Royal Warrant for pay and Promotion, 1926.

Temp. Lt. H. S. Littlepage relinquishes his commn.

J. Ryan and E. S. O'Sullivan to be temp. Lts.

J. M. Ryan to be Lt. on prob.

ARMY DENTAL CORPS.

W. A. McClelland, W. B. Martin, and J. A. McKillop to be Lts. (on prob.).

RESERVE OF OFFICERS.

Lt. S. P. Wilson, from Sup. Res. of Off. R.A.M.C., to be Capt.

TERRITORIAL ARMY.

Hon. Maj.-Gen. Sir Cuthbert S. Wallace (late R.A.M.C.) to be Hon. Col. R.A.M.C. units 47th (2nd Lond.) Div.

ROYAL AIR FORCE.

Temp. Lt. G. M. Titterington, Dental Surg. (temp. Flying Off., R.A.F.), relinquishes his commn.

The name of Squadron Leader H. L. Burton has been brought to notice by Air Vice-Marshal Sir Edward L. Ellington, Air Officer Commanding, British Forces in Iraq, for distinguished services rendered in connexion with the operations against the Akhwan in the Southern Desert, Iraq, during the period November-May, 1928.

INDIAN MEDICAL SERVICE.

Capts. Durgadas Sanyal, Shaikh Mohamed Afzal Faruki, Bhaskar Balwantrao Gadgil, Fazal-ud-Din, Phanindra Nath Basu, Haji Mahommad Salamat Ullah, and Ranjit Sen to be Majs.

Lt. V. A. Edge to be Capt. (prov.).

Maj. A. E. Grisewood, retd., has been granted the rank of Lt.-Col.

Col. F. G. Proudfoot, Asst. Dir. of Med. Servs., 48th (S. Midland) Div., T.A., is apptd. Hon. Surg. to The King, in succession to Col. T. Kay, K.H.S., T.A., ret.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, March 25th.—8 P.M., ODONTOLOGY. Casual Communications: Mr. C. H. Howkins: The Dental Aspects of Radium Treatment. Mr. J. B. Parfitt: A Compound Composite Odontoma. Demonstration: Mr. E. C. Sprawson: Some specimens from the Dental Museum of the London Hospital. (Illustrated by lantern slides.)

TUESDAY.—5 P.M., MEDICINE. Short communications dealing with various aspects of Gastric Chemistry. Dr. Leonard Parsons: The Significance of Achlorhydria in Infancy and Childhood. Dr. S. W. Patterson: The Pathology of Gastric Secretion. Dr. T. W. Turner and Dr. J. F. Venables: The True Frequency of Hyperchlorhydria in Duodenal Ulcer. Dr. T. L. Hardy: The Rôle of Hydrochloric Acid in the Causation of Gastric Pain. Dr. W. M. Roberts: The Effect of Oils on Gastric Secretion. A Discussion will follow.

WEDNESDAY.—5 P.M., COMPARATIVE MEDICINE and NEUROLOGY. Special Discussion on Encephalomyelitis of Man and Animals. Openers: Mr. I. A. Galloway (Comparative Medicine). Dr. J. Godwin Greenfield (Neurology). Dr. W. Russell Brain, Dr. Tom Hare, Mr. Leslie P. Pugh, and others will also speak.

The house and library of the Royal Society of Medicine will be closed from Thursday, March 28th, to Tuesday, April 2nd—both days inclusive.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, March 25th.—8.30 P.M., Discussion on the Medical Indications for the Induction of Abortion and Premature Labour, introduced by Mr. Eardley L. Holland, Dr. B. T. Parsons-Smith, and Dr. Bernard Hart.

HUNTERIAN SOCIETY.

MONDAY, March 25th.—8.30 P.M. (at Simpson's Restaurant, 2 and 3, Bird-in-Hand Court, 77 Poultry, Cheapside). Discussion on: Blood Pressure in Health and Disease. To be opened by Dr. Halls Dally, Dr. Edgar Obermer, and Dr. Temple Grey.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.

WEDNESDAY, March 27th.—4.15 P.M. (at St. John's Hospital 49, Leicester-square, W.C.), Clinical Cases.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.

TUESDAY, March 26th.—5 P.M., Dr. R. A. Young: A Medical Review of the Surgery of the Chest. (Third Lumleian Lecture.)

WEST LONDON POST-GRADUATE COLLEGE, Wes London Hospital, W.

MONDAY, March 25th.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards. 2 P.M., Dr. Trevor Davies: Gynæcological Department.

TUESDAY.—2 P.M., Dr. Shaw: Medical Out-patients. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Hamblen Thomas: Throat, Nose and Ear Department.

WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2 P.M., Mr. Tyrrell Gray: Operations. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Mr. MacDonald: Genito-urinary Department. 2 P.M., Mr. Bishop Harman: Eye Department.

Medical and Surgical Out-patients, Operations, Special Departments, daily, 10 A.M. to 5 P.M., Saturdays, 10 A.M. to 1 P.M. Courses in Anæsthetics and Operative Surgery.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, March 25th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, March 26th.—3.15 P.M., Dr. W. R. Reynell: Demonstration of Neurological Cases.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, March 28th.—4 P.M., Dr. Schlesinger: Jaundice.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, March 26th.—5 P.M., Dr. H. MacCormac: Malignant Growths of the Skin.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

TUESDAY, March 26th.—4.15 P.M., Mr. H. H. Rayner: Cancer of the Colon: Signs and Symptoms and Results of Operation in a series of 60 cases.

Appointments.

GILFILLAN, S. I., M.B., C.M. Edin., has been appointed Medical Superintendent, Bailbrook House Mental Hospital, Bath.

SAVAGE, RONALD, M.B., Ch.B. Aberd., F.R.C.S. Edin., Aural Surgeon at the Lewisham Treatment Centre (L.C.C.).

Certifying Surgeons under the Factory and Workshop Acts: CARTER, R. H., L.R.C.P. Lond., M.R.C.S. (Waltham Abbey District); GARDNER, G. R., L.R.C.P. Edin., L.R.C.S. Edin., L.R.F.P.S. Glasg. (Hyham Ferrers, Northampton); MACKAY, H. A., M.B., Ch.B. Aberd. (Bucksburn, Aberdeen)

Vacancies.

For further information refer to the advertisement columns.

Ashton-under-Lyne District Infirmary.—H.S. At rate of £150.

Bangor, Carnarvonshire and Anglesey Infirmary.—H.S. £200.

Basingstoke, Hants, Park Prewett Mental Hospital.—Jun. Asst. M.O. £350.

Beit Memorial Fellowships for Medical Research.—Jun. Fellows. £400.

Belgrave Hospital for Children, 1, Clapham-road, S.W.—H.S. Also Asst. H.P. Each at rate of £100.

Bexhill, Borough of.—M.O.H. £800.

Birmingham, Queen's Hospital.—Dental H.S. At rate of £50.

Bournville Works.—M.O.

Cambridge, Addenbrooke's Hospital.—H.S. At rate of £130.

Cardiff, King Edward VII Welsh National Memorial Hospital.—Area Tub. Phys. £750.

Cardiff Union, City Lodge Institution.—Third Asst. Res. M.O. At rate of £150.

City of London Hospital for Diseases of the Heart and Lung, Victoria Park, E.—H.P. At rate of £100.

Coventry, Coventry and Warwickshire Hospital.—Hon. Physician.

Dreadnought Hospital, Greenwich.—H.P. and H.S. At rate of £100.

Durham County Council.—District Tuber. M.O. £600.

East London Hospital for Children, &c., Shadwell, E.—Res. M.O. £200. Also Res. H.S. and Cas. O. Each at rate of £125.
Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Asst. Obstetrician.
Evelina Hospital for Children, Southwark, S.E.—H.S. £120.
Exeter, Royal Devon and Exeter Hospital.—H.P. At rate of £130.
Fiji, Gilbert and Ellice Islands Colony.—M.O. £600.
Golden-square Throat, Nose and Ear Hospital, W.—Registrar. Also Clin. Asst.
Hereford, Herefordshire General Hospital.—H.S. £150. Also H.P. At rate of £100.
Hospital for Epilepsy and Paralysis, Maida Vale, W.—Res. M.O. Also H.P. At rate of £150 and £100 respectively.
Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W.—Res. H.S. At rate of £75.
Hull Royal Infirmary.—Third H.S. At rate of £150. Also Hon. Phys.
Lincoln County Hospital.—Jun. H.S. At rate of £150.
Liverpool Port Sanitary Authority.—Asst. Port M.O. £700.
London Female Lock Hospital, 283, Harrow-road, W.—H.S. At rate of £150.
London Temperance Hospital, Hampstead-road, N.W.—H.P. At rate of £100.
Maidstone, West Kent General Hospital.—H.S. £220.
Metropolitan Ear, Nose and Throat Hospital, Fitzroy-square, W.—H.S. £150.
Mildmay Mission Hospital, Austin-street, Bethnal Green, E.—Sen. Res. M.O. At rate of £140. Also Jun. Res. M.O. and Asst. Cas. O. Each at rate of £100.
Newcastle-upon-Tyne, City Hospital for Infectious Diseases.—Res. Med. Asst. £350.
Norwich, Norfolk and Norwich Hospital.—Two H.S's. Each £120.
Oxford, Radcliffe Infirmary and County Hospital.—Hon. Asst. Surgeon.
Penshurst, Cassel Hospital for Functional Nervous Disorders, Swaylands.—Res. M.O. £350.
Plymouth, Central Hospital, Lockyer-street.—Hon. Surgeon.
Poole Borough and Port of.—Asst. M.O.H. £600.
Prince of Wales's General Hospital, Tottenham, N.—Hon. Anæsthetist. £20. Also Hon. Dermatologist.
Princess Louise Kensington Hospital for Children, N. Kensington. H.P. At rate of £75 to £100.
Royal National Orthopædic Hospital, 234, Great Portland-street, W. Hon. Asst. S.
St. Pancras Hospital, 4, King's-road, N.W.—Jun. Asst. Med. Supt., &c. £350.
Samaritan Free Hospital for Women, Marylebone-road, N.W.—Clin. Assts.
Sheffield, Royal Infirmary.—Surgical Registrar. £200.
Southampton, Administrative County of.—M.O.H. £1250.
Stoke-upon-Trent Union, London-road Institution.—Deputy Res. M.O. £400.
Swansea Hospital.—H.S. £150.
Tunbridge Wells and Counties General Hospital.—H.S. £160.
Victoria Hospital for Children, Tite-street, Chelsea, S.W.—Hon. P. or S. for Diseases of the Skin.
Walsall General Hospital.—Jun. H.S. At rate of £100.
West Bromwich and District General Hospital.—H.S. At rate of £200.
Western Skin Hospital, 44, Hampstead-road, N.W.—Hon. Asst. Dermatologist.
Willesden General Hospital, N.W.—Res. H.S. At rate of £100.
Wolverhampton, Royal Hospital.—Res. M.O. At rate of £150.
York, Maternity Hospital and Sanatorium.—Res. M.O. £350.

Births, Marriages, and Deaths.

BIRTHS.

DANSIE.—On March 13th, at Welwyn, Herts, to Marion and Charles Dansie—a son.

DAY.—On March 10th, at Norwich, the wife of Dr. George H. Day, of a son.

HORSFORD.—On March 13th, at Harley-street, W., the wife of Cyril Horsford, M.D., F.R.C.S., of a son.

SHAW.—On March 15th, the wife of Maurice E. Shaw, M.D., of a daughter.

SHELDON.—On March 17th, at a nursing home, the wife of Wilfrid Sheldon, M.D., 22, Wimpole-street, W.1, of a daughter.

DEATHS.

BROWNE.—On March 11th, 1929, at 49, Belgrave-road, S.W.1, James Browne, M.D., aged 69.

BURFIELD.—On March 17th, at Grenofan, Heathfield, Sussex, Thomas Burfield, M.A., M.B.

JAGGER.—On March 16th, after four days' illness, from pneumonia, at his home, Upper Berkeley-street, Portman-square, Walter Jagger, M.B., C.M. Edin.

ORME.—On March 17th, Marie Orme, M.B.E., L.R.C.P.I. & L.R.C.S.I., of Rockside, Matlock, widow of the late Albert L'Estrange Orme, L.R.C.P.I. & L.R.C.S.I. Funeral at Matlock Parish Church, Thursday, March 21st, at 2 P.M.

SHAW-MACKENZIE.—On March 10th, 1929, Charles Frederick Dillon Shaw-Mackenzie, M.B. Edin., fourth son of the late Charles Forbes Wodson Shaw-Mackenzie, of Newhall, Ross-shire.

WALE.—On March 9th, at St. Matthew's-drive, St. Leonards, Malcolm E. H. Wale, L.R.C.P., M.R.C.S.

YOUNG.—On March 12th, suddenly, James Martin Young, M.D., C.M.Aberd., of Calthorpe-road, Edgbaston, Birmingham.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

MAINTENANCE OF LIFE IN ISOLATED MUSCLE.

THE EFFECTS OF ANOXÆMIA.

IN the course of his Ludwig Mond Lecture on the Maintenance of Life and Irritability in Isolated Animal Tissues, delivered at Manchester University on March 6th, Prof. A. V. HILL, F.R.S., justified the use by physiologists of isolated tissues for the study of the problems of the living animal. In medical and physiological progress, he said, improvement in knowledge comes, as it does in chemistry and physics, by the isolation of variables, by studying phenomena in as simple a form as possible, as far removed as may be from the complexity of normal life. He recognised, however, the danger that those who work under artificially simplified conditions may, in their enthusiasm, extend their results too far to practical problems.

He went on: "The greater danger—I speak with feeling—is that their friends, and the daily press, may do so for them. If you describe how a nerve-fibre maintains the electrical potential difference at its boundary by an active process involving the consumption of oxygen, you may find your name in all the newspapers, and be invited to America to raise people from the dead; if you prove that chemical disintegration sets in, in a stimulated muscle deprived of oxygen, you may be charged with attempting to create a living cell (and indeed a living "soul") in the laboratory. There is a real danger, and we academic people must beware of applying our results too far."

With this cautionary preamble Prof. Hill returned to the most difficult problem of all—the cause of a phenomenon which he discovered in 1927—and what follows is in his own words.

About this phenomenon, I speculated last summer, perhaps rather rashly, in the Proceedings of the Royal Society. I say rashly, partly because my paper provoked—via Prof. F. G. Donnan—somewhat undue interest in the public press, partly because the explanation I originally gave may not be sufficient. The facts, however, seem certain and are these. By improvement in technique, which I need not describe now, the rate of resting heat production of a muscle can be measured, in oxygen or in nitrogen. The muscle lies upon the warm junctions of a thermopile, in a thermostat maintained at a constant temperature within a thousandth of a degree, in nitrogen which has been freed from oxygen by passing it over hot copper in a quartz tube. The rate of the resting heat production at 18° C. is (say) 60 g. cm. per gramme per minute; about 1½ thousandths of a calorie. The muscle has previously been washed for some time in salt solution, so that it does not now become spontaneously inexcitable in the manner described by Dulière and Horton. It is stimulated and gives a series of twitches; the heat due to activity is registered by the galvanometer attached to the thermopile; stimulation ends; the galvanometer returns; we should expect it to return, gradually of course, to its original position, the muscle to revert to its original heat-rate. Nothing of the kind. Let me illustrate what happens by a typical experiment:—

Time: A.M. or P.M.	11·56	11·59	12·1	12·2	12·3½	12·5	12·6
Galvanometer deflection: mm.	22	23½	23½	22½	22½	24	23

The muscle was then stimulated by single shocks to fatigue; the galvanometer deflected, and when the stimulation ended, returned to rest once more.

Time P.M.	12·20	12·23	12·25
Galvanometer deflection: mm.	130	130	130

The resting heat-rate in this case has been increased between five and six times. The phenomenon has never failed to appear, and it occurs always in the same quantitative form. The quotient

$$\frac{\text{increment in heat-rate per minute}}{\text{total heat by stimulation}}$$

is always (in the frog's sartorius at 17° C.) of the order of 0·0075. The high heat-rate induced by stimulation is permanent so long as the muscle remains in nitrogen. It may attain 800 g. cm. per gramme per minute after severe fatigue, over 1 calorie per g. per hour. It may remain at this level so long as the muscle is kept in nitrogen, for 24 or even 48 hours, in which time the total heat liberated may be many times as great as can possibly be accounted for by the breakdown of *all* the available carbohydrate into lactic acid. Since, apart from carbohydrate, there is very little except the actual protein of the muscle which we can imagine to break down with such an evolution of heat, we are forced to conclude that the process of anaerobic activity

(or its products) has somehow induced the degradation of the muscle protoplasm itself to bodies containing less total energy.

Resting Heat-rate Drops with Recovery.

If, when the muscle has been fatigued in nitrogen, and its resting heat-rate is high, we admit oxygen, a recovery process sets in as usual, with a considerable evolution of heat. The lactic acid is removed and the muscle is restored to its previous resting condition. This occupies about an hour. If, now, we replaced the oxygen by a stream of pure nitrogen, within half an hour or so diffusion on the one hand, and the resting metabolism of the muscle on the other, have removed the last traces of oxygen from the interior of the muscle substance, and the resting heat-rate in nitrogen can again be measured. Instead of the high value found after stimulation we now observe a low value of the same order of size as before it. The breakdown processes produced by anaerobic activity have been cut short and the muscle has regained its previous steady state. The same treatment can then be applied once more. If the muscle be stimulated to fatigue, its resting heat-rate rises again; if oxygen be again admitted recovery ensues and finally a low value of the resting heat-rate appears as before. There seem to be two alternatives: either (1) the provision of energy by oxidation has restored to their normal state the membranes, interfaces, or agents, which in ordinary life hold apart the unstable reacting substances present in the living cell, which prevent—as I said in my paper—the organised system of the living cell from becoming a biochemical chaos; or (2) in the presence of oxygen some substances have been removed, perhaps by simple oxidation, perhaps by restoration to a precursor, as lactic acid is restored, which, if they be allowed to remain, assist as catalysts, or in some other capacity, in the anaerobic disintegration of the living material. One thing seems certain—the high heat-rate *is* a sign of some kind of irreversible breakdown or disintegration; if it be allowed to continue for a few hours no subsequent restoration of the muscle to its normal excitability is possible, either in oxygen or in oxygenated salt solution.

The phenomena in question are so curious, and the effects so relatively large and so easily demonstrated with the methods now available, that they demand an explanation. I have tested them by every means I could think of and they have withstood the attack. Were they due to a change in the hydrogen-ion concentration caused by the liberation of lactic acid? A resting muscle was immersed in pure CO_2 and its heat-rate remained practically unaltered; the Co_2 must have made it as acid as extreme fatigue. Were they due to a technical error of some kind? a reaction of some fatigue product with the metals of the thermopile? The thermopile was insulated with baked Elo (an artificial resin), shellac, and paraffin-wax; on top of these a piece of tin-foil; and over this a further layer of wax. The phenomenon appeared quantitatively as before. It is inconceivable that breakdown products of muscular activity can penetrate wax, tin-foil, wax, shellac, and Elo, one on top of the other. Was it due to injury in dissection? It was found unaltered in a frog's gastrocnemius, which can be prepared with an absolute minimum of injury. The temperature was lowered to 0° C. The high heat-rate existing in a fatigued muscle diminished to one-sixth, which is what we should expect if it were due to a chemical process occurring continuously, not at all what we should look for were a technical physical error the basis of the phenomenon. Many of my colleagues have witnessed the experiment, and they are agreed that in this respect, at any rate, I am not suffering from delusions. The phenomenon exists; it must be explained, not explained away.

Alternative Explanations.

I was inclined when I first described the phenomenon to the first of the two alternatives I mentioned, to the belief that oxygen restores the normal interfaces, or conditions which prevent the organised system from becoming a biochemical chaos. During the last few months, however, I have come across another effect which inclines me a little to the second alternative—perhaps both are correct. The experiment is a simple one and the result quite certain; it ought to have been made long ago; but one only thinks of these things slowly. If a muscle showing a very high resting heat-rate induced by anærobic stimulation be immersed for an hour or two in *oxygen-free* salt solution, its heat-rate returns to its original low level; the muscle need not even be alive; it may have been "electrocuted" by excessive stimulation, it may have been irreversibly damaged by too long a maintenance of its high heat-rate in nitrogen. Yet, under the influence of the washing, in a time which suggests diffusion outwards of some catalysing agent rather than an immediate effect of contact with a new environment, the breakdown evidenced by the previous high heat-rate is completely—or almost completely—stopped. Clearly, oxygen, as such, is not necessary for a reversal of the effect. Perhaps if lactic acid be not already present in excessive amount the lactic acid breakdown can take the place of oxidation in the maintenance of the normal internal architecture of the cell; perhaps, however, *something* is set free in the absence of oxygen, which induces —or helps to induce—the irreversible breakdown of the muscle protoplasm with a liberation of energy: a something which can be dialysed away by immersion of the muscle in salt water.

It is well known that in man too prolonged exposure to anoxæmia may produce harmful effects lasting for a long time or even permanently. As Haldane writes: "A short exposure, even with loss of consciousness, produces no serious after-symptoms; but occasionally a man's behaviour is very abnormal for a few minutes after recovery. . . . With severe and prolonged exposure to want of oxygen the nervous after-symptoms are of an extremely formidable nature and often end in death. . . . The symptoms are evidently due in the main to widespread injury to the nerve cells during the exposure. . . . The heart may also suffer in prolonged exposure to want of oxygen. The after-symptoms may be mainly cardiac; it may be a considerable time before the heart fully recovers. . . . Probably every other organ and tissue in the body feels the after-effects of severe exposure to want of oxygen. The patient often enough dies of pneumonia. Acute nephritis and gangrene of extremities have been noted." And so on. May we not be witnessing here in man the after-effects of the same partial disintegration of the living protoplasm as can so easily be demonstrated in anoxæmia in the isolated muscle?

Further Evidence of Harm from Oxygen Lack.

In another direction, this time in the strips of embryonic tissue studied by Warburg, we find evidence of a harmful effect of oxygen lack. An embryo of a chick is kept for some hours in salt solution saturated with nitrogen; oxygen is then introduced. In the normal embryo there is practically no lactic acid formation if sufficient oxygen be present; the free energy required for continued existence is maintained by oxidation. In the embryo, however, which has been subjected to a period of anoxæmia, the capacity for oxidation is diminished and a large part of the energy it requires must now be derived from the lactic acid breakdown. By anoxæmia, in fact, the normal embryo has been reduced to a state in which its metabolism is similar to that which Warburg has found to characterise tumour tissue. Can it be, as Warburg's work suggests, that oxygen lack working upon the normal architecture and machinery of the cell leaves behind a type of mechanism which leads in the end to the formation of tumour tissue? Dare we see in the disintegrative process produced by anaerobic activity in the isolated muscle cell an exaggerated case of the harmful effect produced in man by prolonged and severe anoxæmia, in the chicken embryo by oxygen want? It is dangerous to speculate too far, but it is foolish not to speculate at all.

I had hoped to be able to tell you the results of further experiments. If the increment in the resting heat-rate produced by anaerobic stimulation be really due to the presence of some diffusible chemical substance liberated in activity, then an extract of, or the dialysate from, a fatigued muscle might produce the same increment without stimulation. Experiments of this kind are being performed, but they have led, as yet, to no decisive result. It may, however, be possible by such means to explore the subject further. We may be able to decide whether in guarding the cell against disintegrative change the lactic-acid breakdown can, as in other respects, take the place of oxidation. To-day I can but indicate the complexity of the problem, the importance of the mechanisms here seen dimly at work, and the depths of our present ignorance of them.

NATIONAL BABY WEEK COUNCIL.

THE annual general meeting was held at Carnegie House on March 13th under the presidency of Sir Gomer Berry, chairman of the Council. He said that the chief aim of the Council's existence was the creation and establishment of a sound public opinion about maternity and child welfare, and this was achieved not only by general propaganda but also through intensive work by the members, who best knew the needs of their own areas. The Council had carried on its activities for 12 years, and was now linked up with some 70 national societies, but its regular income was totally inadequate for its needs. Sir Gomer then presented the challenge shields and other awards for local baby week campaigns in 1928, the Lady Astor shield for the great towns being won by Kettering, and the William Hardy shield for smaller areas by Hill and Cakemore.

Dr. Eric Pritchard, in presenting the annual report, said that the three points on which special attention had been concentrated in the 1928 campaign were: (1) immunisation

as a means of protecting young children against disease; (2) prevention of maternal mortality; (3) new developments in maternity and child welfare work. He spoke with appreciation of the help given by volunteers, by the press, and by certain commercial firms.—Dr. A. Stuart Hebblethwaite (M.O.H. for Sunderland) said he considered ignorance a prime factor in the suffering and ill-health among babies. Last year Sunderland's infant mortality-rate fell below 90 for the first time, but unfortunately the figure had been doubled in the first two months of this year, owing to measles, influenza, colds, and the great poverty prevailing.

Mr. Percy Gates, M.P., gave an address on the Development of the Child Welfare Movement and Block Grants. Since 1918, he said, the public health services had been working under a percentage system of grants, those grants being based on the expenditure of the local authority concerned. Under the Local Government Bill the Exchequer grants were to be paid to counties and county boroughs according to the needs of the locality estimated on a formula, and not according to expenditure. Though Mr. Gates had been responsible for introducing an amendment in the committee stage in the House of Commons to exclude maternity and child welfare services from the block grant provision—which amendment had not been adopted—he paid a tribute to the great consideration shown by the Minister of Health in his willingness to adopt certain safeguards, and admitted that he had made out a strong case for the alteration of the system. It was now for those interested in child welfare to use their influence in their own localities by serving on public bodies as well as on voluntary committees, to make the service as efficient as possible.

THE POSITION OF SUSSEX HOSPITALS.

THE last day of February brought to a close the annual meetings of the hospitals in Sussex whose year ends on Dec. 31st. Almost all of them say that their premises must be extended if they are to cope with the growing demand. At the same time they have to record a certain amount of indifference among the general public as gauged by the subscriptions.

On Feb. 28th Brigadier-General d'A. G. Brownlow said that as long as the *Royal Sussex County Hospital* had to go on gambling on free legacies the financial position could not be regarded as satisfactory. The governors were faced with a mountain of apathy. The report showed that the decrease in the number of patients admitted to the in-patient department and the increase in the average number of beds occupied and length of stay in hospital which was so noticeable in 1927 had continued in 1928. Some two-thirds of the in-patients underwent operations in the theatres, and the strain on the surgical and nursing staffs had been enormous. The theatres were no longer adequate for the work, and the 2181 operations had been performed in precisely the same space as was deemed sufficient for the performance of some 800 when the present suite was built 25 years ago. Mr. Bernhard Baron was going to give £5000 towards the provision of a new operating theatre, and the work would be put in hand as speedily as possible. There had also been a great increase, said General Brownlow, in the work of the pathological and bacteriological department, and the governors had reluctantly determined to close the school of massage, as it would be necessary to secure a considerable increase of accommodation to meet modern requirements and to secure an economical number of students, and this could not be found. The ordinary income had failed to meet ordinary expenditure by £5302, but owing to legacies a credit balance of £5580 was shown on the income and expenditure account. The result of the centenary appeal fund for £100,000 had been very disappointing, producing only £45,000, of which £10,000 was given by Mr. Bernhard Baron. The rise of rates was stated to have largely accounted for the average cost of each in-patient per week going up by 3*s*. 7*d*.

The *Royal Alexandra Hospital for Sick Children* in Dyke-road, Brighton, has now 100 beds, as compared with 74 in previous years. Its income in 1928 was insufficient to meet the expenditure by £744, and the annual report stated that at least another £1000 a year was required to meet the ordinary annual expenditure.—The *Sussex Eye Hospital* has appealed for £25,000 to bring the institution up to date. It is hoped to increase the number of beds from 30 to 50.—The *Sussex Maternity and Women's Hospital* is to be enlarged by the erection of a second new labour ward. The fact that no fewer than 143 patients attended the private wards last year is held to show that they fulfil a useful purpose. The institution's rates have not yet been paid for 1928, but the governors recorded their appreciation of the sympathy of the Finance Committee of the Brighton Corporation with regard to the assessment.

At the annual meeting of the *Brighton and Hove Dispensary* the chairman of the committee said hospitals were constantly being told to keep abreast of the times, and surely the best way to bring that about would be to relieve hospitals of the heavy burden of rates. Nearly 6500 out-patients were treated during 1928 and over 1600 visits were made to the homes of patients. At Hove Hospital the in-patients numbered 392 and the casualties 1635.—At the annual meeting of the *Sussex Throat and Ear Hospital* regret was expressed that the extension decided upon some years ago could still not be proceeded with. It was stated that the building fund, although it now amounted to £2650, did not justify beginning the work. The practice of the hospital is steadily increasing, but ordinary expenditure considerably exceeds ordinary income.—The *New Sussex Hospital for Women and Children* at Brighton, which is entirely staffed by women, has opened a new wing free from debt. The hospital is carrying out investigations in conjunction with three other hospitals on the treatment of cancer with radium. It is to be incorporated as a limited association, not for profit, and it is hoped to make the hospital a training school for nurses in the near future.

The *Queen Victoria Cottage Hospital at East Grinstead* records an improvement in the financial position as the result of an urgent appeal. The need of extension is said to be very pressing, but a scheme involving an expenditure of £8500 has had to be turned down, as the money is not forthcoming.—Extensions at *Worthing Hospital* since 1924 have cost nearly £41,000. The year's working shows a deficit of £656, and the fact that only £1150 came in by annual subscriptions is considered unsatisfactory in a town of the size and importance of Worthing.

ALLERGIC PHENOMENA IN RHEUMATISM.

IN an annotation last week entitled New Views on Rheumatism in Childhood attention was called to the possibility of rheumatism being in the nature of an allergic reaction. Dr. G. Arbour Stephens writes to recall an article in the *Medical Journal and Record* for Feb. 17th, 1926, wherein he described an anaphylactic condition, determined by the bites of insects, in relation to rheumatic fever.

THE WORK OF No. 3 CANADIAN GENERAL HOSPITAL.

THIS is just the book[1] that any one who served, or lost a relative who served, in No. 3 Canadian General Hospital would be glad to possess. It follows all the moves, retells all the events that in retrospect have come to mean so much, and reproduces many photographs of people and scenes that will bring a thrill. The book gives a good account of the history of the unit from its conception by its first commanding officer, Col. H. S. Birkett, in October, 1914, through its arrival in France on June 18th (Waterloo Day), 1915, to its return to Montreal on July 4th, 1919, after what Sir Arthur Sloggett, the Director-General in France, described as splendid service, during which it had dealt with 143,762 admissions. The first chief of the Medical Section was Lieut.-Colonel John McCrae, whose beautiful lines established the cult of the Flanders poppy, and who died of pneumonia just after his promotion to be Consulting Physician in the British Army. The hospital did most of its work at Boulogne, where it suffered much in air-raids, but pulled its weight in the heavy work of the force and materially helped in advancing the knowledge of medicine and surgery and the care of the wounded. We would have gladly seen more of the diary of Private McMutchkin (p. 21) who was wounded in the Salient, but as the doctor said it was in the Rolandic area, supposed he must have been moved there when unconscious! Several abstracts of valuable scientific papers are preserved in the book; the coolness of the nurses under fire and their self-denying care of their patients during air-raids is recorded, also the Christmas and other festivities, and our only regret is the want of an index of people and matters. Everyone distinguished seems to have wanted to see this hospital and to have been pleased with what he saw.

ROYAL WESTMINSTER OPHTHALMIC HOSPITAL.

A PARAGRAPH on p. 568 of our last issue briefly reported the proceedings at the first annual meeting of the Royal Westminster Ophthalmic Hospital to be held at the new premises in Broad-street, W.C. By inadvertence the name of the hospital was confused with that of the Western Ophthalmic Hospital, whose in-patient department is now temporarily housed in the Hospital for Epilepsy and Paralysis, Maida Vale, whilst out-patients attend at 264, Edgware-road, W.

[1] No. 3 Canadian General Hospital (McGill). 1914–19. Edited and compiled by R. C. Featherstonhaugh. With a foreword from Field-Marshal H.R.H. The Duke of Connaught. The Gazette Printing Company, Montreal. 1928. Pp. 274. $5.

Goulstonian Lectures

ON

POLYURIA

Delivered before the Royal College of Physicians of London

BY ERNEST BASIL VERNEY, M.B. CAMB., F.R.C.P. LOND.,

PROFESSOR OF PHARMACOLOGY IN THE UNIVERSITY OF LONDON, UNIVERSITY COLLEGE.

LECTURE II.*—EXPERIMENTAL REDUCTION OF RENAL TISSUE.

(Delivered on March 12th, 1929.)

MR. PRESIDENT AND FELLOWS.—In my last lecture I attempted to show that the polyurias associated with isolation of the kidney, with diabetes insipidus, and with water ingestion had an immediate ætiology which was common to all—namely, a decline in the content of the blood in the antidiuretic hormone normally secreted by the pituitary body. We saw that at the height of the diuresis the total molecular concentration of the urine was an extremely low one, and stress was laid on the rapid decline in the chloride concentration in the urine, a decline which proceeded to a degree such that it was scarcely possible to detect the presence of this substance in the urine. Moreover, the ebb of the chloride percentage synchronised with the flood of the water excretion. These facts demonstrated quite clearly that this type of polyuria was distinct both in its nature and ætiology from that elicited by a rise in blood pressure. In this latter case a rise in the rate of water excretion is invariably accompanied by a movement of the composition of the urine towards that of the plasma, and the specific gravity of the urine in like manner creeps not towards 1000, the value for distilled water, but towards 1009, the value for the protein-free filtrate of the plasma. I mention these facts again since it is in terms of what may be called a "pressure" diuresis that I believe the proximate explanation of the polyuria of chronic nephritis will ultimately be found.

It is, Sir, with considerable diffidence that I stand here to describe some experiments, performed recently by Miss Pickford and myself,[5] which I believe to have some bearing on the fundamental observations which you yourself made on the effects of reducing, by surgical means, the amount of kidney tissue in the dog, observations which you communicated to this College in your Goulstonian Lectures 31 years ago.[3] You showed [2] that the removal of amounts of renal substance up to two-thirds of the total was compatible with prolonged survival of the animal, and that even when the amount removed was as small as one-eighth to one-quarter "it was exceptional for the urine to return at all exactly to its original quantity and density, the most usual condition being one where the urinary water was distinctly increased in amount." Further, in the non-fatal cases in which the excision of a wedge from one kidney was followed one to six weeks later by the removal of the other kidney, the increase in the output of urine became more marked as the result of the second operation, and this increase was the one striking and constant phenomenon. The increase was observable within 24 hours of the operation and was not only considerable but also persistent, being present, for example, two years after the removal of the second kidney. Further, the urine became very pale and the specific gravity fell from the normal value, ranging between 1050 and 1030, to a figure varying between 1007 and 1020. No albumin nor sugar was present in the urine and the animals remained in good health. There was no increase in the amount of urea excreted but a slight increase in the percentage of urea in the blood was detected. Such animals, however, were unable to excrete a concentrated urine, and if very large amounts of nitrogenous food were given, the urea formed was readily excreted but only at the expense of a still further increase in the amount of urine. To quote from one of Rose Bradford's papers:—

> "The cause of the increased excretion of urinary water when the amount of available kidney is thus reduced is by no means clear; it is, however, not associated, as far as my observations have gone, with any very great increase in the general blood pressure." [3]

It is the feeling that the experiments which I propose to describe have some bearing on the mechanism of the production of this polyuria which constrains me to put before you some results which I believe are not entirely devoid of interest or importance in their pathological bearings.

The problem as to whether the whole of the blood passing through the kidney traverses of necessity the glomerular tufts was first attacked by William Bowman, who states the conclusion to which he arrived in the following words [1]:—

> "All the blood of the renal artery (with the exception of a small quantity distributed to the capsule, surrounding fat, and the coats of the larger vessels) enters the capillary tufts of the Malpighian bodies; thence it passes into the capillary plexus surrounding the uriniferous tubes, and it finally leaves the organ through the branches of the renal vein. . . . With the inconsiderable exceptions just mentioned, the terminal twigs of the artery correspond in number with the Malpighian bodies. . . . The blood leaving the Malpighian tufts is conveyed by their efferent vessels to the great renal reservoir, the capillary plexus surrounding the uriniferous tubes. . . . The vessels lie in the interstices of the tubes and everywhere anastomose freely so that throughout the whole organ they constitute one continuous network lying on the outside of the tubes, in contact with the basement membrane."

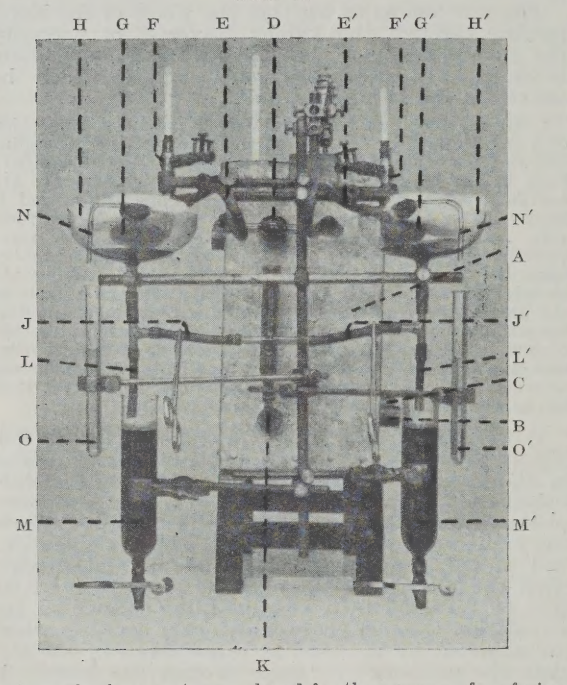
Bowman's original observations on the blood-supply to the kidney have been repeatedly confirmed in more recent years, and it may be taken as established that his conclusions form a correct statement of the facts. There is, then, no anastomosis between the branches of the renal artery. Their ramifications end in the glomerular tufts, and any interference with the blood flow through one of these branches will be reflected in a corresponding change in the circulation through those Malpighian capsules which are supplied by it. And in consequence of the fact that the network of vessels around the tubules is capillary in character, the capacity of one part of the network to feed any adjacent part is extremely limited. The occurrence and character of infarcts in the kidney bear adequate testimony to the rigidity of this restriction in that they demonstrate the dependence of a tubule for its blood-supply on the patency of its respective glomerular tuft, or at least on the transmission of blood through those glomeruli which preside over tubules in its immediate neighbourhood. Bowman clearly recognised and described the repetitive character of the architecture of the kidney and doubtless realised that the functional response of the kidney at any time was the integral of the responses of its individual units. The physiology and pathology of urinary secretion may therefore be approached from two closely related standpoints. On the one hand the reactions of the renal unit to changes in its environment may be studied and an attempt made to determine in what manner and to what extent these reactions are modified by the incursions of disease; on the other the nature and degree of the functional association, if such exists, between the structural units of the kidney may be made the primary object of study. On the one hand the reactions of the unit are deduced from a study of the effects of imposing a stimulus which is evenly distributed throughout the colony, on the other the stimulus is applied to certain members only of the community and the responses of the remaining members are determined. In the one case the individual, in the other the society forms the basis of study, and that there is some local means of

* Lecture I. appeared in THE LANCET of March 16th.

coördination within this society is, as we shall see later, extremely probable.

We have seen that the immediate cause of the polyuria in Rose Bradford's experiments was by no means clear. It was therefore of interest to determine whether the functional removal of portions of tissue from the kidney when perfused in the isolated state, and therefore entirely removed from any influence which might be exerted on it through the intermediation of the central nervous system or of the metabolic activities of other glands, would be followed by any change in the secretory activity of the remainder. The simplest way in which this could be accomplished was clearly by the ligature of one of the branches of the renal artery since, as we have seen, by so doing the region supplied by this branch

FIG. 1.



Photograph of apparatus employed for the purpose of perfusing two kidneys in parallel. (For description see text.)

should become completely anoxæmic and, in consequence, cease to function. It was therefore decided that a primary branch of the renal artery should be ligatured during the perfusion of the kidney in the isolated state and the effects on the rate of flow and composition of the urine determined. Some preliminary experiments showed that such a procedure was unaccompanied by so great a fall in urine flow as would be expected on purely anatomical grounds; indeed, on some occasions the rate of urine elimination actually increased as the result of arresting the circulation through approximately 50 per cent. of the total kidney substance. But the interpretation of such experiments was difficult, in that it was found impossible to assess at all accurately the changes in rate of flow and composition of the urine from the values which these would have exhibited had there been no interference with the blood-supply to a part of the kidney. One could compare the sample of urine collected immediately before the branch was ligatured with that immediately following, but such would not yield a truly quantitative index of the effects of applying the ligature, since the physiological state of the kidney itself was slowly undergoing changes during the whole course of the experiment. This is a difficulty inherent in all those experiments of a biological nature in which an attempt is made to interpret quantitatively the effects of producing an irreversible change of state. The difficulty may be overcome in one of two ways. Either the experiments are performed on a large scale and the results subjected to statistical treatment, or the experiment is rigidly controlled by the *simultaneous* conduction of another, the two experiments being carried out under conditions as nearly identical as it is possible to devise and maintain. Fortunately, the kidney is a bilateral organ, and it was decided to explore the possibility of perfusing the two kidneys of one dog with the heart-lung preparation, in the hope that the two kidneys so perfused would secrete urines at approximately the same rate and of approximately the same composition. This was found experimentally to be the case. The apparatus which has been employed is shown in Fig. 1.

The venous reservoir, peripheral resistance, and the warming coil through which the arterialised blood passes to the kidneys are placed inside the water thermostat A. This is maintained at constant temperature by an electrical hot point, and by such means variations in the temperature of the circulating blood are almost entirely eliminated. The blood from the venous reservoir leaves the tank A through the tubulure B. Thence it passes to the cannula in the superior vena cava of the dog, which lies to the right of the apparatus. The brachiocephalic cannula is connected through the tubulure C with the variable peripheral resistance within the thermostat, and the blood having traversed the resistance, returns to the venous reservoir. From the high-pressure side of the resistance blood passes through a warming coil and leaves the tank through the tubulure D, whence it is distributed via the tubes EE′ and cannulæ FF′ to the renal arteries of the two kidneys GG′ resting in the glass vessels HH′. The venous blood from the kidneys runs back to the venous reservoir via the tubes JJ′ and K. The blood flow through the kidneys can be determined at any time by moving the Spencer-Wells forceps from LL′ to the position shown in the figure. The blood then passes into the graduated vessels MM′ and the time required for the delivery of 50 c.cm. is measured. The cannulæ NN′ are tied into the ureters and the urine is collected in the graduated tubes OO′.

The two kidneys from a dog are thus being perfused under identical conditions, and it is found under favourable circumstances that the rates of blood flow through the kidneys, the rates of urine elimination and the compositions of the urines are approximately the same on the two sides. Fig. 2 demonstrates the truth of this statement. During the early part of the experiment the blood pressure was maintained constant and the gradual rise in the water-output and fall both in chloride and urea percentages are well seen. Further, it will be observed that the graphs representing these urinary changes on the right and left sides follow one another faithfully. At the point M a sudden and severe change in the conditions of perfusion of the two kidneys was made by the addition of a large volume of freshly defibrinated blood to the circulation, combined with a lowering of the arterial blood pressure. The responses of the two kidneys to the infliction of so intense a change in their environment are practically identical and run parallel the one to the other until the conclusion of the experiment, which lasted more than two hours. Further, the rates of blood flow through the two kidneys showed a close approximation and reacted to the above changes to a degree which was almost identical on the two sides. Other control experiments demonstrated the quantitative similarity in the responses of two kidneys to such stimuli as were produced through the addition of urea, sodium sulphate, or pituitrin to the circulating blood. My object in stressing these experiments is to show that in such a preparation as has just been described we are provided with two isolated kidneys which may be considered to be strictly in the same physiological state, in that both the past history and present condition of the one correspond accurately to those of the other. If, then, a change of state, even an irreversible one, is produced locally in the one kidney, the effects of this change may be quantitatively determined simply by reference to the conduct of the other kidney, which is functioning throughout as a simultaneous control. It is with this, the heart-lung-double-kidney preparation, that Miss Pickford

and I [5] have begun an investigation into the effects on the function of one part of the kidney of arresting the circulation through the remainder.

The renal artery of the dog divides into two main branches of approximately equal size near the hilum of the kidney, one branch supplying the anterior half, the other the posterior half of the organ. When one or other of these branches is ligated there is, as would be expected, a marked fall in blood flow through the kidney, a fall, moreover, which, as we shall see later, corresponds accurately to the diminution in the amount of functioning tissue. The urine flow, however, shows no comparable diminution, indeed quite commonly an absolute increase in its rate is encountered, an increase, moreover, which is immediate in its onset. It seemed that we were here dealing with a very remarkable phenomenon, a phenomenon which was not embraced by current theories on the mechanism of the secretion of the urine, and therefore demanded a closer study. It will, I think, make the conclusions which we are inclined to draw from this study, in so far as it has been carried up to the present time, more intelligible if a description of an actual experiment is given, and the results of this experiment depicted in a concrete form. The results of such have been collected in Fig. 3. The rates of blood flow through the two kidneys, the rates of urine flow, and the percentages of chloride and of urea in the urine from each kidney are charted in order from above downwards. In the initial part of the experiment, as far as the point M, it is seen that the two kidneys are secreting urines which are practically identical both as regards their rates of flow and as regards their content in chloride and in urea. Moreover, the blood flow through the right kidney is, within the limits of accuracy of the measurement, the same as that through the left. At the point M a ligature which had earlier been placed loosely around the anterior primary branch of the right renal artery was securely tied. The blood flow falls precipitously to a new value which is in point of fact 51 per cent. of the rate it exhibited immediately before the tying of the ligature. Approximately 50 per cent. of the right kidney was therefore suddenly excluded from the circulation. But this extreme interference had no detectable influence on the rate of urine elimination. The urine continued to flow for a time at the same rate as that secreted by the left kidney, and then gradually climbed away from the control rate as is shown by the divergence of the continuous from the interrupted line of water excretion. On arresting the circulation through half of the right kidney, therefore, the remaining half suddenly, and without a moment's hesitation, doubled its previous rate of secretion. The degree of the polyuria on the right side showed a progressive increase throughout, and immediately before the close of the experiment the rate of secretion of the half of the right kidney was 30 times as great as that of the whole of the left kidney. The thin continuous line H in the figure shows the rates at which the half of the right kidney would have secreted had arrest of the circulation through the remainder been without influence upon it. The values so plotted are 51 per cent. of the control rate of urine flow on the left side, since there was a 49 per cent. reduction in blood flow on the right side as the result of ligaturing the arterial branch. In some experiments the rate of urine flow fell as the result of interrupting the circulation through part of the kidney, but this fall never approached the calculated rate. In other words, arrest of the blood-supply to one part of the kidney invariably produced a relative increase in the flow of urine, and not infrequently an absolute increase, from the other part. Passing now to the chloride figures, it will be seen that no appreciable change was produced in the percentage of chloride in the urine by ligaturing the arterial branch. The amounts of chloride excreted per unit interval of

I and L, Chloride (as NaCl) in right and left urine respectively in mg. per 100 c.cm. N and O, Urea in right and left urine respectively in mg. per 100 c.cm. M, 300 c.cm. fresh defibrinated blood added.

The figures on the chloride and urea graphs represent the amounts (in mg.) secreted per 15 minutes. The time of a plotted point is the mean time of the interval during which the sample of urine was collected.

time increased, however, on account of the polyuria which we have just been considering. It will be observed that in this experiment the chlorides are extremely low percentually, and it is an experimental fact that when such is the case the effect of an increase in perfusion pressure in causing the typical approach towards the chloride concentration of the plasma, is small or even entirely absent. In other experiments of this type there has been an increase more or less definite in the percentage of chloride eliminated. The minute output, however, always shows a relative increase, sometimes even, as in this particular experiment, an absolute increase. Further, it will be seen that the reduced kidney gave a much more marked response to a rise in perfusion pressure in so far as concerned its rate of chloride secretion, an important fact to which we shall have occasion later to return. The effects, then, on the chloride excretion of a functional reduction of such a degree in the renal tissue may be summed up by saying that there is invariably a relative increase and quite commonly an absolute increase in the minute output. At high blood pressures this absolute increase becomes, as far as our observations have gone, invariable.

A very different state of affairs, however, is encountered when we come to consider the output of urea in such an experiment. The figure shows quite clearly that ligature of the arterial branch is followed immediately by a profound fall in both the percentage and absolute amounts of urea eliminated. But if we calculate the absolute amount which should have been eliminated by the reduced kidney on the assumption that the perfused part is secreting at the same relative rate as the control kidney, the theoretical figures so obtained are a little lower than those actually found by experiment. (Compare the figures showing the absolute amounts of urea excreted with the bracketed figures adjacent to them.) The excretion of phenol red or of indigo carmine shows a reaction to the functional reduction in the renal tissue comparable to that of urea.

Towards the end of the experiment charted in Fig. 3, 100 mg. of indigo carmine were added to the circulating blood, and the post-mortem appearances of the transversely bisected kidneys are reproduced in Fig. 4. None of the dye was seen in the infarcted region of the right kidney with the exception that traces were visible as short and narrow streaks at the points A and B. The sharp line of demarcation between the perfused and infarcted zone is well seen, and particular stress may be laid on the difference in intensity of the blue colour in the two kidneys, the surface of the reduced kidney exhibiting a paler or, as one of my technical assistants appropriately expressed it, "a more washed-out appearance" than that of the control kidney.

Before discussing the significance of these changes in composition of the urine, it is essential that we should determine whether the polyuria which is observed arises, as has so far been assumed, as the lone result of a functional change in the perfused part, or is due to the secretion of a dilute solution of chloride by the infarcted region which may still receive a small blood-supply via the capsule, or through the intertubular capillary anastomosis, or through both. It is of interest that Hermann [4] in 1862 observed in 3 out of 18 experiments an absolute increase in the urine flow following ligature of the renal artery in dogs. He states: "Unter 18 Versuchen zeigte sich dreimal die auffallende Erscheinung, dass nach Schliessung der Ligatur der Harn ununterbrochen und sogar mit grösserer Geschwindigkeit als früher, abgesondert wurde." The increase was attributed by him to an exceptionally generous supply of blood to the kidneys through collateral channels, since in all the other experiments the urine flow

D and E, Blood flow through right and left kidney respectively in c.cm. per minute. F and G, Urine flow from right and left kidney respectively in c.cm. per 15 minutes. H, Theoretical rate of urine flow from right kidney in c.cm. per 15 minutes (see text). I and J, Chloride (as NaCl) in right and left urine respectively in mg. per 100 c.cm. K and L, Urea in right and left urine respectively in g. per 100 c.cm. M, Anterior primary branch of right renal artery was ligatured at this point. The figures on the chloride and urea graphs represent the amounts (in mg.) secreted per 15 minute interval of time. The figures in brackets are the theoretical amounts of urea secreted by the right kidney calculated on the basis of the measured diminution in blood flow (see text). (L. M. Pickford and E. B. Verney.)

stopped when the blood-supply to the whole kidney was arrested. It seems not improbable that in the case of these three experiments of Hermann, ligature of the main arterial supply evoked an increased functional response by small portions of the kidney which were receiving a supply of blood, adequate to their needs, from those few and scattered interlobular vessels which perforate the capsule and inosculate with vessels in the perirenal fat. Unfortunately in his paper he gives no analysis of the urine before and after ligature of the renal artery, so that it is impossible to interpret with confidence these few results of his in terms of those which we are now discussing, although an interpretation along these lines would seem to be not unreasonable.

But that the capsular supply to the infarcted region of the isolated kidney is in no way connected with the production of the polyuria which we have observed is completely proven by the following observations. Firstly, in all the experiments in which a dye was added to the blood before the close of the experiment and after the arterial branch had been ligatured, the pigment in the reduced kidney was limited to the perfused region, the line of demarcation being extremely well defined. Moreover, the intensity of the pigment was much less in the reduced kidney than in the control, corresponding with the lower concentration of dye in the urine from the former than in that from the latter. This last observation in so far as the difference in tint of the cortex of the two kidneys is concerned is not alone conclusive evidence, since the capacity of the tubular epithelium to concentrate the dye within it might be affected in the reduced kidney without there being of necessity an accompanying increase in the rate of urine elimination. (See Fig. 4.) Secondly, the responses already described as resulting from ligature of a branch of the renal artery are not affected by stripping the capsule from the infarcted region and thereby eliminating entirely any supply of blood through this agency.

There still remains the possibility of there being a slow flow of blood from the perfused to the infarcted region through the extensive intertubular capillary plexus, and of the cells in this latter region secreting, in consequence of so abnormal a circulation, a dilute solution of chloride along with a trace of urea. Such an explanation of the facts is disproven completely by the observation that if a dye such as phenol red be added to the blood before the arterial branch is ligatured, the medulla of the infarcted region as seen at the end of the experiment is darker in tint, not only than the neighbouring part of the medulla, but also than the medulla of the control kidney.

It may be taken as established, therefore, that after a primary branch of the renal artery has been ligatured under the conditions of these experiments, the urine secreted originates solely in the part of the kidney, the blood-supply to which has not been interfered with. The infarcted region takes no share in its production. But the urine is, as we have seen, markedly changed both in rate of flow and in composition, and in attempting to arrive at a more detailed knowledge of the means whereby this increase in flow is achieved, it is clearly essential to know whether the pressure and rate of flow of blood in the one part of the kidney are altered from their previous values by arresting the blood-supply of the other part. In those experiments in which a dye was added after the arterial branch had been ligatured it was quite easy at the end of the experiment to dissect off the cortex of the kidney and to weigh the stained and unstained portions. The percentage reduction in the renal cortex could in this way be compared with the percentage reduction in blood flow consequential to ligature of the arterial branch. The two percentages were found to be almost identical. No appreciable change in blood flow through the one part of the kidney, therefore, occurred as the result of arresting the circulation in the other part. Further, the ligation of the vessel led to a small rise, 1 to 2 mm. Hg, in the general arterial pressure, which was, of course, transmitted to the control kidney and could be immediately neutralised if desired by adjusting the artificial peripheral resistance of the preparation. But, more important, a saline differential manometer connected to the perfusion cannulæ near their insertion into the renal arteries showed no appreciable pressure difference when the branch of the one renal artery was ligated. There was, it is true, a slight rise on the ligatured size owing to the retardation in the blood flow through the cannulæ, but the change was only 3 or 4 mm. of saline, of entirely the wrong order of magnitude to effect such gross changes of urine flow

FIG. 4 (*a*).

from the reduced kidney as we have already observed to occur.

The vascular condition in the one part of the kidney, therefore, in so far as the arterial pressure, blood flow, and total resistance are concerned, remain unaffected when the blood-supply to the other part is arrested.

I do not propose to discuss at this juncture the mechanism by which the one part of the kidney becomes cognisant of the infarction of the other and immediately responds by secreting urine at a faster rate. But that there is some means other than through their blood-supply by which the functions of the secretory units of the kidney are continuously integrated seems an unavoidable deduction from the facts which have been presented. We are able, however, to form a clear idea of the nature of the stimulus which the one part of the kidney receives from the neighbouring infarcted region. We saw in the last lecture the effects on the rate and composition of the urine of an increase in the pressure at which blood was supplied to the kidney. To-day we have observed the effects of circulatory arrest in the one part of the kidney on the rate and composition of the urine secreted by the other part. The effects are qualitatively identical. The reduced kidney then responds at constant blood pressure exactly, so far as our observations go, as though it were being subjected to an increase in perfusion pressure. If, as seems probable, the glomerulus is the receptor of the pressure stimulus and the intermedium through which this stimulus becomes effective in initiating, and controlling the rate of, the secretion of the renal unit of which it forms a part, the increase in the urine flow could be explained in terms of a shift of a given quantity of resistance from the vasa afferentia to the vasa efferentia. Such a shift would presumably entail an increase in the glomerular capillary pressure without there being any changes in the general blood pressure or the blood flow through the non-infarcted region, potential changes which, as we have seen, are absent in these experiments. This is one way in which the facts can be interpreted. There are others, but it would be unprofitable to discuss them at this juncture.

We suggest that the polyuria which we have observed from the isolated kidney as the result of arresting the blood-supply to a part of it, is of similar ætiology to the polyuria observed by Rose Bradford in his survival experiments on the surgical removal of portions of kidney tissue from the dog. The nature of these experiments necessarily precluded any conclusions being drawn as to whether the responses of the reduced kidney were initiated locally, reflexly, or through the intermediation of some chemical substance locally or remotely produced. The rapidity of the responses of the kidneys both in Rose Bradford's experiments and in our own, in the one case observable within 24 hours, in the other case immediate, and the qualitative similarity in the changes in composition of the urine in the two cases, suggest that there is behind the production of both some common underlying cause. If this be so it is difficult to resist the belief that in such experiments a coördination of a mutually *inhibitory* nature exists between the various parts of the mammalian kidney, perhaps between even the individual units of which it is composed. An hypothesis involving coördination through the intermediation of the nervous tissues in the kidney would seem to fit most easily the experimental facts in so far as they have been obtained up to the present. But such an assumption is extremely speculative, and whatever the mechanism by which this local adaptation is brought into being, its results are perfectly definite, and may be summed up by saying that the pressure stimulus to secretion has become more effective. If one part of the kidney is functionally removed from the field of activity, the remaining part develops intrinsically just that stimulus which previous knowledge tells us is the most effective in producing an increased flow of urine.

It will have already been noticed that there is a marked relative increase in chloride, not infrequently indeed an absolute increase, following a reduction in the functioning renal tissue. The increase in the output of urea, however, relative to the concomitant tissue reduction is small and, as we have seen, the absolute output is invariably and markedly diminished as compared with the output of the control kidney. Such a preparation then is exhibiting a condition of urea retention with little or no retention of chloride. The specific gravity and composition of the urine from the functioning part are approaching those of the protein-free filtrate of the plasma. The part of the kidney which is secreting more urine is undoubtedly performing more work than before—calculation shows that this is so in the case of the isolated kidney—and it shows signs of failure in so doing. For just as the heart, both when it is called upon to perform more mechanical work, and while its tone is diminishing under a constant load, responds by dilating, so the kidney responds to an increase in the intensity of the applied stimulus or to a decrease in its tone by secreting a fluid, the composition of which moves towards that of the plasma. Dilatation in the case of the heart and "pressure" diuresis in the case of the kidney are comparable phenomena. The functioning part of the reduced kidney is therefore under a condition of greater strain than before, and it no longer possesses the responsive capacity of the whole. That this is so can be well seen in experiments on the heart-lung-double-kidney preparation. Sodium sulphate, for example, causes a much smaller diuresis from the reduced kidney than from the control kidney. Similarly, the antidiuretic action of pituitrin is much less marked in the reduced than in the control kidney. The question whether the response is reduced to exactly the same degree as the substance of the kidney has not yet been thoroughly investigated, but it seems quite clear that a rise in blood pressure produces per unit of functioning tissue a greater increase in urine flow in the case of the reduced kidney than in the case of the control. Each unit in the functioning part of the reduced kidney has therefore become more sensitive than before to the pressure stimulus—witness the rise in chloride to which reference was made earlier—whilst it is not clear that its capacity to respond to an increased concentration of urea or sulphate in the blood is in any way altered. Whether the increased response of a unit in the reduced kidney is occasioned by a shift in resistance from the vas afferens of the glomerulus to the vas efferens, a hypothesis which was put forward earlier in this lecture to account for the absence of any change in blood flow through the one part of the kidney when the blood-supply to the other part was arrested, we do not know. Such a hypothesis would necessarily carry with it an increase in the glomerular capillary pressure, and an increase in the rate of filtration through the glomerulus, if such indeed be one of its functions. But I should like here to emphasise the fact that filtration through the glomerular capillaries in mammals has not been proved to occur, and it would seem in the present state of knowledge to be unwise to close one's eyes to the possibility of some mechanism other than that of filtration affording the means of communication between the pressure stimulus and the effector cells of the tubules. We here confine our attention to the responses of the secretory unit as a whole, and do not attempt to differentiate these responses into functions of its individual parts.

I propose now, if I may, to summarise in as brief a form as possible the main points to which attention has been directed in this lecture, and the conclusions which may legitimately be drawn therefrom.

Functional removal of a part of the renal tissue leads, as Rose Bradford has shown, to a polyuric response by the remaining part. Since a similar phenomenon is encountered in the case of the isolated kidney, it is probable that the mechanism involved in its production is the same in both cases, and that the results of a study of the response in the isolated organ may justifiably be transferred to the interpretation of the response obtained by Rose

Bradford in the whole animal. In the isolated kidney the mechanism culminating in this response is a strictly local one and is not entirely of a chemical nature. The response itself is immediate. The changes in the composition of the urine show that the stimulus to the functioning parts of the reduced renal tissues is similar in nature to that produced by a rise in blood pressure. There is developed, then, locally, just that stimulus which we know to be the most effective in increasing the flow of urine. This increase in the stimulus entails the expenditure of more energy by the renal units concerned, and the increased work which they are called upon to do is accompanied by their partial failure. This failure is manifested in an approach in the composition of the urine towards that of the protein-free plasma, the "urine" of complete renal failure, with the consequential difficulty in the excretion of adequate amounts of urea and relative ease in the elimination of chloride. Lastly, we have seen that the responsiveness of the reduced kidney to the addition of such substances as sodium sulphate or pituitrin to the blood is impaired to a very marked degree.

With the bearing of these facts on the pathology of chronic nephritis and the means whereby the kidney, gradually deprived of its reserves, strives to maintain to the end its primary function of maintaining the constancy of composition of the "milieu interne," it is proposed to deal in the next lecture.

POST-OPERATIVE GASTRIC ACIDITY.

BY E. CHARLES LINDSAY, C.B.E., F.R.C.S. ENG.,
SURGEON WITH CHARGE OF OUT-PATIENTS, LONDON HOSPITAL;
AND
WILLIAM EVANS, M.D., M.R.C.P. LOND.,
MEDICAL FIRST ASSISTANT AND REGISTRAR TO THE HOSPITAL.

MANY and varied are the theories advanced to explain the ætiology of progressive peptic ulceration of the stomach and duodenum. Devitalisation of the mucosa by infection and the presence of hydrochloric acid and pepsin have each been apportioned their respective rôles in the production of localised proteolysis resulting in ulceration. Workers in this field of research have added in support of their views a wealth of experiments; nevertheless, the true pathogenesis of gastro-duodenal ulceration remains undiscovered. Still more conflicting are the views advanced to explain the healing of peptic ulcers. The neutralisation of the gastric acid by alkalies and its absence or neutralisation following the operation of gastro-jejunostomy have each been cited as the modus operandi of cure, in the former instance by medical means and in the latter by surgical. Bolton [1] emphasised the part played by gastric acidity in healing the ulcer. Paterson [2] stated that after gastro-jejunostomy there was diminution of the total chlorides with an almost constant increase in the mineral chlorides of the gastric contents, an important factor in reducing gastric acidity and thus promoting healing of the ulcer. Bolton and Goodhart [3] maintained that the absence of free hydrochloric acid or the presence of a low active hydrochloric acid curve are no indications, when taken alone, that the gastric secretion is correspondingly diminished, for the total chlorides may still be at the normal height, the readings being the result of free duodenal regurgitation and similar to those of successful gastro-enterostomy cases. It is generally assumed that gastro-jejunostomy causes a marked diminution in the gastric acidity value. In fact, the curative effect of this operative procedure on gastric and duodenal ulcers is usually ascribed to the reduction of gastric acidity after the operation.

From the study of post-operative cases attending the "follow-through department" it was thought that the achlorhydria which existed in many instances immediately after the operation of gastro-jejunostomy for the cure of a duodenal ulcer did not persist, and that the conception of the cure of gastric or duodenal ulceration as solely or primarily a question of removing or neutralising the acid was erroneous. A series of cases was therefore investigated, and the results are embodied in this paper.

Material and Technique.

A study was made of 60 cases, 49 of whom are males and 11 females. In all instances the operation of gastro-jejunostomy had been performed for the cure of a chronic duodenal ulcer. The gastric acidity was estimated after the Ewald test-meal. Estimation by the fractional method was impracticable, as most of the patients were unwilling to submit to an investigation which would detain them for three hours or more. Only those subjected to the Ewald type of test-meal before and after operation were therefore called up for the third or late post-operative test-meal. Out of 149 cases invited to attend for this further test of the gastric acidity only 60 responded; of the remainder 15 had left the neighbourhood and could not be traced, 3 had died of intercurrent diseases, 1 was reported to have died at another hospital following an operation for perforation of a chronic gastric ulcer; many assured us of their fitness since the operation and considered any further investigation of their cases unnecessary; others did not reply. The present investigation, however, is not intended to be a statistical study of the results of gastro-jejunostomy, as the observations are confined to the functions of the stomach after gastro-jejunostomy with special reference to gastric acidity.

It was at one time thought that X ray examination of the stomach after the opaque meal would be a valuable adjunct to the study of its functions, but the results obtained by other workers have been disappointing. Smithies,[4] investigating a number of cases by this means, concluded that, apart from demonstrating the patency or closure of the pylorus or gastro-jejunostomy stoma and the recognition of some of the complications following the operation, little reliable information about gastric function could be obtained.

In the following series of cases the acidity values are expressed in terms of free HCl and total acidity, the free HCl being estimated as grammes per 100 c.cm. and the total acidity determined in terms of c.cm. N/10 HCl.

The interval between the pre-operative test-meal and the operation varied usually from one to seven days. The early post-operative test-meal was taken about 14 days after the operation and immediately before the patient's discharge from hospital. The late post-operative test-meal was carried out after a period of six months to eight years after the operation; in 53 cases the interval was two years or longer, whilst in 26 instances four years had elapsed since the early post-operative test-meal.

In 59 cases posterior gastro-jejunostomy and in one case an anterior retro-colic gastro-jejunostomy had been performed. Occlusion of the pylorus was not practised in any of the cases. Cholecystectomy had been carried out in two cases, and in 30 the appendix had also been removed. Appendicectomy did not appear to affect the post-operative gastric acidity in any way. All the operations were carried out either by Mr. James Sherren or by one of us (E. C. L.). It is found convenient to arrange the cases in four groups depending on the relationship between the acid values found in the early and late post-operative test-meals. In the first group are included cases where free hydrochloric acid was absent in the early but present in the late post-operative test-meal. In Group 2 are placed the cases where free hydrochloric acid was found at both post-operative test-meals. Cases

showing achlorhydria immediately after operation and also on re-examination are included in Group 3, whilst those having free acid in the early but no free acid at the late post-operative test-meal are listed in Group 4.

GROUP 1. *Free Hydrochloric Acid Absent in the Early but Present in the Late Post-operative Test-meal.*

Fifteen cases—i.e., 25 per cent.—fall into this group; 12 are males and three females. Their ages range from 35 to 68 years, the average being 48. There was an interval of two years in all cases—and over four years in nine cases—between the early and late post-operative test-meals. The lowest acidity value was 0·07 per cent. free hydrochloric acid; in ten patients it was 0·1 per cent. or over, and in six it was 0·15 per cent. or greater. In one it had increased to 0·22 per cent., the interval between the test-meals in this case being three years; the pre-operative acid value had been 0·17 per cent. Thirteen patients were free from symptoms and in perfect health, one had vague symptoms, and the other, who complained of much abdominal discomfort and vomiting, had a strong alcoholic history, the acidity values in these two cases being 0·11 per cent. and 0·18 per cent. free acid respectively.

From a study of this group it will be seen that the condition of achlorhydria found immediately after operation may not, and does not, persist in the majority of cases, and that the persistence of achlorhydria is not a necessary factor in the complete alleviation of the patient's symptoms after gastro-jejunostomy. It further shows that the gastric acidity may have a higher value at the late post-operative test-meal, although the operation has relieved the patient completely of all symptoms.

GROUP 2. *Free Hydrochloric Acid Present in Both Post-operative Test-meals.*

Twenty-five cases fall within this group—23 males and two females. The ages vary from 26 to 64 years; the average age is 42. The interval between the early and late post-operative test-meals was two years or more in 22 cases, and over four years in eight. The lowest acidity value recorded in this group is 0·06 per cent. free hydrochloric acid; 21 had a free acid value of 0·1 per cent. or over; in 11 it was 0·15 per cent. or greater, whilst in four the free value varied from 0·2 per cent. to 0·24 per cent. The acidity value in the late post-operative test-meal remained the same as that in the early post-operative test-meal in two cases, was higher in 15 and lower in 8. Twenty-one patients in this group are free of symptoms. Of the remaining four one has symptoms pointing to the presence of an anastomotic ulcer; in this instance the free acid value is 0·18 per cent., and the total acidity 62; but the patient will not consent to further surgical measures. Three have indefinite dyspeptic symptoms; one of these, a heavy smoker, finds that he is free from all symptoms when he abstains from smoking; another has a strong alcoholic history.

A study of this group again emphasises the unreliability of the early post-operative test-meal as an indication of the true post-operative gastric acidity, the acid value as shown in the late post-operative meal being considerably higher in 15 cases.

GROUP 3. *Free Hydrochloric Acid Absent in both Early and Late Post-operative Test-meals.*

Eleven cases are placed in this group—seven males and four females. The ages vary from 28 to 69 years, the average age being 45. In eight cases the interval between the second and third test-meals exceeded two years, whilst in four a period of four years or more had elapsed. Eight were free from symptoms; indefinite subjective symptoms were present in the remaining three.

It is clear from a study of the figures obtained that the persistence of the state of achlorhydria in this small group is in no way dependent on the acid value in the pre-operative test-meal. The free hydrochloric acid value in the pre-operative meal may be as high as 0·31 per cent., and exceeds 0·2 per cent. in five instances.

GROUP 4. *Free Hydrochloric Acid Present in the Early and Absent in the Late Post-operative Test-meal.*

Nine cases fall in this group—seven males and two females. The ages range from 35 to 64 years; the average age is 47. In five instances the interval between the second and third test-meals was four years or more and it was two years in eight cases. In eight instances the free hydrochloric acid value was found to be greater than 0·1 per cent. in the early post-operative test-meal. Eight were in perfect health; the remaining patient with free acid value of 0·04 per cent. complained of vague abdominal pain coming on ten months after the operation.

Relationship between the Pre-operative and Early Post-operative Acidity.

It has been repeatedly claimed that, if gastro-jejunostomy is to cure gastric or duodenal ulceration, it must produce a state of achlorhydria as shown by test-meal immediately after operation. That a reduction in free hydrochloric acid generally occurs, and that absence of free hydrochloric acid may also be noted in the early post-operative test-meal, is admitted. This investigation, however, seems to show that undue stress has been laid on the importance of this finding in prognosis. Sherren [5] stated that gastro-jejunostomy should immediately abolish the free hydrochloric acid and diminish the total gastric acidity by one-half to two-thirds; that such a condition resulted in 90 per cent. of cases; that in these success was certain, and that the acidity remained permanently lowered. He stressed the importance of the test-meal 14 days after operation and viewed with gravity a result which showed no decrease in the acidity, and pointed out the susceptibility of such a case to anastomotic ulceration.

In the present series achlorhydria was established at the early post-operative test-meal in only 26 cases—i.e., 43 per cent. In many the reduction was not appreciable, and in five cases there was an actual increase in the acidity value at the early post-operative test-meal compared with the pre-operative value. Furthermore, these five patients remain in good health and free from symptoms after periods varying from two to five years after the operation. The average decrease in the free hydrochloric acid value amongst all the cases was 0·13 per cent. When the relationship between pre-operative test-meal and the late post-operative test-meal is considered the average decrease in free hydrochloric acid value is found to be 0·1 per cent. Nine cases showed an increase in the acid value.

Significance of Achlorhydria in Post-operative Test-meals.

Absence of free hydrochloric acid was found at the late post-operative test-meal in 20 cases—i.e., in over 33 per cent. In 11 of these achlorhydria was also found at the early post-operative test-meal and had persisted for a period varying from 12 months to eight years, whereas in 15 cases the achlorhydria recorded in the early post-operative test-meal did not persist and free hydrochloric acid was present on re-examination. These figures are in marked contrast to the results obtained by Lewisohn and Gunzberg,[6] who found absence of free hydrochloric acid at the late post-operative test-meal in only two out of 69 cases. They advocated that the operation of partial gastrectomy, which produced a state of achlorhydria in 75 per cent. of cases, should replace gastro-jejunostomy in the surgical treatment of gastric or duodenal ulceration. Hunter [7] found that complete achlorhydria resulted from gastro-jejunostomy in about 50 per cent. of cases.

The present investigation seems to establish that the operation of gastro-jejunostomy produces "temporary achlorhydria" in 25 per cent., "persistent achlorhydria" in 18 per cent., and "delayed achlorhydria" in 15 per cent. of cases. In those classified as temporary achlorhydria free hydrochloric

acid was absent in the early and present in the late post-operative test-meal. Cases showing the presence of free hydrochloric acid in the second test-meal and absence in the third are referred to as those showing delayed achlorhydria, whilst those exhibiting achlorhydria at both post-operative test-meals are the cases grouped as persistent achlorhydria.

Neutralisation of the acid gastric secretion by the regurgitation through the stoma of the alkaline contents of the duodenum is put forward by the majority of investigators to explain this post-operative state of achlorhydria. Such a theory, however, fails to explain why achlorhydria found in 15 cases at the early post-operative test-meal did not persist, why achlorhydria found at the late post-operative test-meal in nine cases was not also present at the early post-operative test-meal, and why the operation in 25 instances did not produce a state of achlorhydria either in the early or late post-operative test-meals. It is well established [7 8] that when hæmatemesis is an added factor in local disease of the stomach a reduction in the acidity value or even achlorhydria is the rule; in the same way local gastric hæmorrhage due to trauma at the time of operation may be instrumental in producing a state of achlorhydria or reduced gastric acidity in the early post-operative test-meal.

Relationship between Post-operative Acidity Value and the Patient's Health.

MacLean, Jones, and Fildes[9] state that "after a successful gastro-enterostomy the contents of the stomach are generally alkaline, or very much reduced in acidity; but should the operation afford no relief to the patient it will be found that the stomach contents still remain highly acid, such an observation suggesting that the benefit to the patient arising from a successful gastro-enterostomy is in large measure dependent on a change in reaction produced by the mechanical alterations brought about by the operation, this alteration presumably resulting from the neutralisation of the acid by the alkaline pancreatic contents, passing directly to the stomach via the stoma, such a change assisting the healing of the ulcer." Lewisohn and Gunzberg,[6] as the result of their investigation, concluded that "post-operative achlorhydria was most desirable, that a patient leaving the hospital with an absence of free hydrochloric acid is not going to have any recurrence of symptoms, and that patients in whom this achlorhydria has not been established require close observation." The results of the present investigation lend no support to these views. Hunter[7] found (*a*) that when the free hydrochloric acid was abolished 50 per cent. of the cases remained free from symptoms while others complained of pain and vomiting; (*b*) that when free hydrochloric acid was present or high, 64 per cent. remained perfectly well; and (*c*) that though high gastric acidity was a constant association of gastro-jejunal ulceration, recurrent ulcer occurred in the stomach when the free hydrochloric acid was reduced below the limits of the normal or abolished.

In order to facilitate the study of the relationship between the post-operative acidity value and the patients' health it will be convenient to arrange the cases in five groups according to their acidity values. In the first group are placed 20 cases which demonstrated achlorhydria at the late post-operative test-meal; of these 16 were free from symptoms and four had symptoms of an indefinite character. Nine cases with free hydrochloric acid under 0·09 per cent. form the second group; here seven were in perfect health whilst two complained of some abdominal discomfort at intervals. Twelve cases with free hydrochloric acid value ranging from 0·1 per cent. to 0·14 per cent. make up the third group; seven of these are without symptoms and five complained of vague abdominal discomfort in attacks, although they all stated that they were much benefited by the operation. In the fourth group are 14 cases in which free hydrochloric acid was present in a concentration of 0·15 per cent. to 0·19 per cent.; of these 11 were in perfect health, two had vague symptoms, whilst one with free hydrochloric acid value of 0·18 per cent. had symptoms which suggested the presence of an anastomotic ulcer; he gave a strong history of alcoholism and had refused to undergo another operation. In the last group are placed the remaining five cases where the free hydrochloric acid value varied from 0·2 per cent. to 0·26 per cent.; two of these complained of occasional mild indigestion and three were in perfect health. Analysis of these figures demonstrates that of the cases where the free hydrochloric acid value was less than 0·15 per cent. indefinite symptoms were present in 26 per cent. and similarly, where the free hydrochloric acid value varied from 0·15 per cent. to 0·26 per cent., vague dyspeptic symptoms occurred in 26 per cent. It appears, therefore (1) that high post-operative acidity is not incompatible with perfect health; (2) that a high post-operative acidity does not necessarily favour the production of anastomotic ulceration; and (3) that the operation of gastro-jejunostomy brings about the healing of a progressive peptic ulcer in some other way than by reducing the gastric acidity value. Lastly, it should be noted that 44 of the 60 cases remained in perfect health, the operation having thus effected a complete cure in 73 per cent. Moreover, with one exception, the remaining patients assured us that although some dyspeptic symptoms persisted, they had been able to carry out their occupations without ill-health since the operation, and were feeling very much better. It should be remembered that the percentage of cases cured would have been very much higher had the patients who refused to present themselves for the late post-operative test-meal on account of their state of well-being after the operation been included.

Effect of Alkali Therapy on Acidity Value.

It is not intended to dwell on the merits or demerits of alkalies in the treatment of gastro-duodenal ulceration, but the possibility that the administration of alkalies influenced the gastric acidity value was kept in view and a careful note was made of the therapeutic measures adopted in each case. All cases had been subjected to a course of alkali treatment for varying periods before the first or pre-operative test-meal. This treatment had been carried out either by the patient's medical attendant at home or at the out-patient department of the hospital, and in some instances in the medical wards. The alkali mixture invariably prescribed contained grs. 10 of bismuth oxycarbonate, grs. 25 of magnesium carbonate, and a similar quantity of sodium bicarbonate, and this was given three or four times daily. The pre-operative test-meal demonstrated the free hydrochloric acid value to be 0·15 per cent. or over in 51 cases and in 30 to be 0·2 per cent. or greater. In the interval between the pre-operative and early post-operative test-meals no alkalies had been prescribed in any of the cases in this series, so that any change in the acidity value at the second examination was the immediate result of the operation. After the early post-operative test-meal each patient left hospital with a month's supply of the bismuth mixture. Inquiry at the time of the third test-meal proved that the cases free from symptoms had taken no further alkalies, and those with slight subjective symptoms had taken their medicine only occasionally over short periods; in these the acidity varied. In one case, where achlorhydria was found at both post-operative test-meals, the patient had taken bismuth regularly for a period of two and a half years, but a similar state of achlorhydria had persisted in ten others who had taken no alkalies. No alkalies were administered on the day of the test-meal. It appears, therefore, that alkali therapy produces no permanent reduction in the gastric acidity value as shown by the Ewald test-meal either before or after operation.

Effect of Smoking and Alcohol on Acidity Value.

Dixon [10] pointed out that tobacco-smoking, by stimulating the autonomic system, increases the secretion of the alimentary glands, and later, after the smoking has ceased, depresses them. Hurst [11] regards tobacco-smoking as one of the most frequent causes of

hyperchlorhydria; whilst Rolleston [12] emphasises the relative sensitiveness of the individual as an important factor in determining whether or not a heavy smoker will develop symptoms of gastric disease. In the present investigation an attempt was made to discover whether smoking was a factor in influencing permanently the gastric acidity value. For this purpose the cases are classified as non-smokers, moderate smokers, and heavy smokers; 15 were non-smokers, 20 moderate, and 25 heavy smokers. The average free hydrochloric acid value in the first group was 0·05 per cent., in the second group 0·12 per cent., and in the third 0·1 per cent. This at first sight seems to indicate that the gastric acidity value is higher in smokers than in non-smokers, but such a deduction would be fallacious, since free hydrochloric acid was present in seven non-smokers, and in three of these the value exceeded 0·1 per cent., whilst achlorhydria was present in seven heavy smokers.

Similarly, attention was paid to the daily consumption of alcohol by each patient in order to ascertain its influence on gastric acidity; 22 were total abstainers, 4 were moderately heavy drinkers, and the remaining 34 took alcohol in moderation and usually only at week-ends. No definite relationship was found to exist between the intake of alcohol and the acidity value.

The "Time Factor": Its Influence on Post-operative Acidity.

The difference between the early and late post-operative acidity values was noted in each case; the mean increase or decrease was then calculated over consecutive periods of six months after the early post-operative test-meal. The results obtained were plotted and the curve demonstrated a sharp rise in the acidity value for two and a half to four and a half years after operation, followed by a rapid fall up to eight years after operation. No great importance is assigned to this curve.

Conclusions.

1. The state of achlorhydria found in the early post-operative test-meal may not, and in 58 per cent. of cases does not, persist. 2. The post-operative acidity value may in some instances exceed that found in the pre-operative test-meal, the operation, nevertheless, having completely relieved the symptoms. 3. The early post-operative test-meal taken 14 days after operation is an unreliable measure of the true post-operative gastric acidity and therefore is of no great value. 4. A persistent achlorhydria, as shown by the absence of free hydrochloric acid at both post-operative test-meals, occurs in 18 per cent. of cases. 5. The establishment of a state of achlorhydria, as found in the early post-operative test-meal, is in no way dependent on the acidity value found at the pre-operative test-meal. 6. Some factor other than the neutralisation of the acid gastric contents by regurgitation of the alkaline duodenal contents through the stoma appears to be instrumental in the lowering of the post-operative acidity value. 7. Temporary achlorhydria may be produced by the hæmorrhage incidental to the operation, and this to a large degree may account for the unreliability of the early post-operative test-meal as truly depicting the post-operative acidity value. 8. The theory that the healing of duodenal ulceration with complete alleviation of the patient's symptoms after gastro-jejunostomy is brought about by the neutralisation (partial or complete) of the gastric acidity is not borne out by the present investigation. 9. A high post-operative gastric acidity, even in concentration of 0·25 per cent. free hydrochloric acid, is not incompatible with perfect health. 10. A high post-operative gastric acidity is not a fruitful cause of anastomotic ulceration. 11. Alkali therapy, smoking, and the taking of alcohol appear to have no constant effect on the acid value as shown by the Ewald test-meal either before or after the operation. 12. It seems that the acid value tends to increase up to four years after the operation and then to decrease, but such a finding should not be unduly emphasised, as only a few patients reporting five to eight years after the operation were investigated.

We are greatly indebted to Dr. P. N. Panton, Director of the Hale Clinical Laboratory, for the analysis and estimation of the acidity in all the cases. Our gratitude and thanks are also due to the sisters of the wards, who so willingly helped with the administration of the test-meals.

CHORDOTOMY

SECTION OF THE ANTEROLATERAL TRACTS FOR THE RELIEF OF PAIN, WITH NOTES OF SEVENTEEN CASES.

BY GEORGE F. STEBBING, M.B., B.S. LOND.,
SENIOR ASSISTANT MEDICAL OFFICER, LAMBETH HOSPITAL, S.E.

THIS communication is a record of the operation of section of the anterolateral tracts of the spinal cord for the relief of pain. After dealing with certain points in the technique of the operation, attention will be directed especially to the cases suitable for the procedure, the immediate and later results, the extent and duration of the relief afforded, and the mortality.

The history and bibliography of the operation has been so fully set out by Donald Armour in his Lettsomian lectures [1] that it is unnecessary to refer to it here. It will suffice to say that in 1912 Spiller and Martin [2] reported a case in which the anterolateral columns of the spinal cord were divided for the relief of pain due to malignant disease.

In view of the few cases that have been reported it does not appear that the operation has been done very often, although patients for whom it may be useful are numerous enough. The following observations are based on 17 patients under my care on whom the operation has been performed since February, 1922. Eleven were suffering from inoperable carcinoma of the rectum or uterus, five from tabes dorsalis, and one from a painful stump following amputation through the hip-joint, performed for sarcoma of the femur.

The Operation.

The level at which the anterolateral columns were divided has varied with the disease from which the patient was suffering. In those who had carcinoma, the section was made opposite the sixth dorsal vertebra; in four patients who had gastric crises of tabes dorsalis the section was made opposite the third dorsal vertebra; in one who had lightning pains of tabes dorsalis in the lower limbs, the section was made opposite the fifth dorsal vertebra; and in the patient with causalgia the section was made opposite the sixth dorsal vertebra. In all the patients except the last mentioned the section was made on both sides of the cord.

The level having been decided upon the cord was exposed by laminectomy of two vertebræ. In some of the earlier cases the laminæ of three vertebræ were removed, but it was not found to make the operation easier, ample exposure being obtained through two. It was found necessary, in order that the front of

[1] THE LANCET, 1927, i., 691.
[2] Jour. Amer. Med. Assoc., 1912, lviii., 1489.

the cord could be easily seen, to remove the whole of the laminæ so that there should be no "overhang" at the sides. The dura was then incised along the whole of the exposed length and the arachnoid lifted and divided. The point of the dentate ligament nearest to the centre of the wound was caught in fine-toothed forceps and divided, and the posterior and anterior nerve roots of two segments were identified. The cord was then rotated by gentle traction on the dentate ligament until the anterior median groove could be seen. A fine grooved needle was inserted into the lateral aspect of the cord at a point midway between the posterior nerve root and the anterior median groove. The needle was passed to a depth of about 3 mm. and the handle was then raised and the point made to emerge from the cord between the anterior root and the median groove and made to engage in the dura in front of the cord. The needle served two purposes—first, to mark the limits of the section; and, second, to steady the cord while the cut was made. I am indebted to Sir Charters Symonds for suggesting this manœuvre to me. A fine von Graefe's knife was next passed along the groove of the needle, and the fibres outside the needle divided. In most of the cases there was no bleeding, but in one or two there was enough blood to obscure the field; it was found, however, that by waiting a few minutes the bleeding stopped without it being necessary to use swabs or to handle the cord. The other side of the cord was then dealt with in the same way. Some of the earlier cases complained of girdle pain at the level of the section and, to avoid this, in all the later cases the posterior nerve roots immediately above the section have been divided. The dura was closed by fine unchromicised catgut sutures and the muscles sutured in layers and the skin closed by continuous salmon gut.

The position and extent of the section of the cord made differs a little from that described by Donald Armour and other writers. With the help of Dr. J. R. Perdrau a study was made of a large number of cords in which various tracts had degenerated, and from the observations made it was concluded that all the pain fibres would be included if the knife entered midway between the posterior root and the median groove instead of midway between the anterior and posterior roots. Passing the needle as described above the cut is not carried quite so deeply into the anterior horn as is shown in Armour's diagram. The area divided is indicated in the figure, which is taken from a photomicrograph made by Dr. Perdrau. It represents a section, at the level of the fifth dorsal segment, of the spinal cord of a patient who had compression myelitis. The black lateral areas are the degenerate lateral tracts, and it will be seen that the incision clears them by a safe margin and divides the whole of the anterolateral tracts.

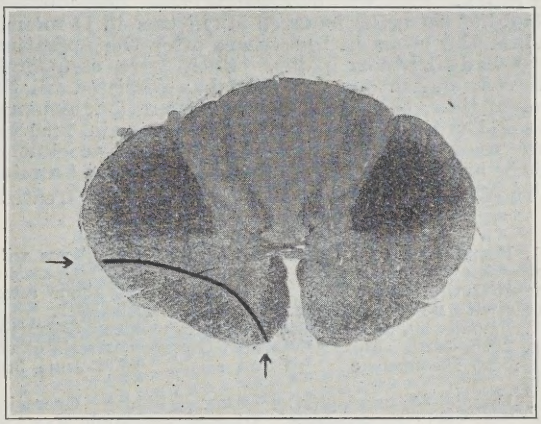
After-treatment.

After the operation the patients were kept lying down for a week, but were encouraged to turn on either side and to lie prone. Sometimes there was a tendency to retention of urine requiring the use of a catheter eight-hourly for a few days but except in one case, described below, the patients were able to pass their urine naturally within a week. As all the patients were in poor health general massage was started on the third day, and the patients were allowed out of bed at the end of a week and given general baths of ultra-violet radiation with the object of shortening convalescence as much as possible. The wounds all healed satisfactorily.

After-effects.

The operation was only undertaken in patients who had such severe pain that a major operation was justified for its relief. They were, therefore, all bad subjects for, but only two died as a result of, the operation. One died of pneumonia on the third day; Dr. Perdrau, the pathologist in this case, expressed the opinion that the pneumonia was of more than three days' duration, and that it had been overlooked before the operation. The other fatal case, a woman, aged 73, with carcinoma of the cervix, died on the seventh day of paralytic ileus; after the operation she had no pain, had no paralysis of the legs although the knee-jerks were absent, the plantar reflexes gave a flexor response, and she passed urine naturally. Her bowels, however, were obstinately constipated and resisted all efforts to overcome the ileus. It was probably inadvisable to perform the operation in so old a patient.

In two patients there was complete paralysis of the legs for a few days and in several a paresis of the legs, sometimes lasting for two or three weeks. It was noted that this paresis was most marked and prolonged in those cases in which the cord was most "handled," and in the later cases care was taken to touch the cord as little as possible. In several cases,



Section of fifth dorsal segment of a patient who had compression myelitis. The dark areas are the degenerate lateral tracts. The arrows indicate the points of entrance and emergence of the needle and the line encloses the fibres that are divided by the operation. (Photomicrograph by Dr. Perdrau.)

particularly those with tabes dorsalis root pains, at the level of the section, were severe enough to be troublesome and to require the administration of pyramidon or morphia. In only one case, however, did the root pains persist, and in that case they had lasted up to the present time, 18 months after the operation. Bedsores occurred in some of the carcinoma cases, but in none did they appear soon enough to be considered due to the operation. They only occurred when the patients were dying and did not appear worse than those which occur in patients suffering from similar disease on whom the operation had not been performed.

Relief of Pain.

The nature and purpose of the operation was carefully explained to all the patients, and in all but the two fatal cases inquiry was made as to whether they thought the relief obtained was enough to compensate them for having undergone the operation and its subsequent discomfort. In every case the reply was in the affirmative, and in many cases their replies were enthusiastic and obviously sincere. Some of them appeared to have expected too much of the operation and were disappointed when the cancerous cachexia was not relieved; it was noted, however, that owing to the relief of pain and the discontinuance of morphia which many of them had been taking there was a marked improvement for a time in the general condition.

There was sometimes complete relief from pain for many months, but in others the relief was only partial, and several stated that pain had gone from everywhere except a particular spot. One, for example, a patient with carcinoma of spine, pelvis, and other bones, secondary to a breast that had been amputated with no local recurrence, lived three years after the operation and complained of pain

at a point on the inner side of one foot. Another on whom the operation was performed for the relief of severe intrapelvic sciatic pain caused by recurrent carcinoma of the cervix that had been treated by radium, after the operation had severe pain "of a boring character" in the left great trochanter (which had not existed previously) but no pain anywhere else.

Some of the patients did not live as long after the operation as had been expected. But these were all suffering from advanced carcinoma, and prognosis in such cases is notoriously difficult. The five patients suffering from tabes dorsalis deserve separate consideration. One had complete relief of the gastric crises for which the operation was done, but died 3½ months later from pyelonephritis which antedated the operation. She was up and about, and was not incontinent between the operation and her death. Two, who had gastric crises, had complete relief, but the crises recurred in one case in 14 months and in the other in four years after the operation. Two had lightning pains. Both were completely relieved, and in one the relief has persisted till the present time, 18 months after the operation, although he still has girdle pain. In the other the pains recurred four years after the operation, and on account of this he has recently been admitted to another hospital.

The following is a brief account of the cases treated:

Malignant Disease.

1. Female, aged 39, carcinoma of cervix of uterus with metastases in lumbar spine and pelvis. Operation August 10th, 1922. Pain relieved; up and about afterwards with no incontinence. Died Nov. 20th, 1922.

2. Female, 30, carcinoma of cervix of uterus. Operation Oct. 26th, 1922. Pain relieved; temporary paresis of the legs; no incontinence; up and about. Died June 3rd, 1923.

3. Female, 47, carcinoma of cervix of uterus. Operation May 3rd, 1923; no paralysis. Died of pneumonia May 7th, 1923.

4. Female, 40, carcinoma of lumbar spine, pelvis, and other bones, secondary to a breast that had been removed. Operation May 31st, 1923; pain relieved except in one foot. Relief continued till death Feb. 11th, 1926.

5. Male, 62, carcinoma of rectum. Operation Nov. 19th, 1923; retention four days and paresis of legs till Dec. 6th. Died Dec. 26th, 1923.

6. Female, 40, painful stump after amputation through hip-joint. Operation one side only, 1923; pain relieved; six months later patient was seen and was complaining of girdle pain. Subsequent history not known.

7. Female, 73, carcinoma of cervix. Operation Feb. 18th, 1924; no retention and no paralysis of legs, but had paralytic ileus. Died Feb. 25th, 1924.

8. Female, 39, carcinoma of cervix of uterus. Operation Feb. 24th, 1926; no retention but weakness of the legs; some pain afterwards in the left leg. Died March 20th, 1927.

9. Male, 68, carcinoma of rectum. Operation March 11th, 1926; some weakness of the legs lasting for a month; retention of urine followed by cystitis. Died April 25th, 1926.

10. Female, 63, carcinoma of cervix uteri with vesical fistula. Operation August 20th, 1928; pain relieved; paresis of legs for three weeks; bedsore appeared Sept. 17th. Died Oct. 4th, 1928.

11. Female, 43, carcinoma of cervix of uterus. Operation August 22nd, 1928; retention of urine for three weeks; some weakness of legs; pain relieved. Still alive.

12. Female, 38, carcinoma of cervix of uterus, recurred, after radium treatment, in pelvis and inguinal glands. Operation Dec. 3rd, 1928; pain relieved, but now has pain in left trochanter only. Still able to be up and about.

Tabes Dorsalis.

13. Female, 38, gastric crises; cystitis and pyelonephritis. Operation Feb. 11th, 1922; pain relieved; no paralysis. Died of pyelonephritis May 23rd, 1922.

14. Male, 47, lightning pains and morphinism. Operation Nov. 13th, 1924; slight paresis of legs; relief of pain but complained of girdle pain at site of operation; pains recurred 1928.

15. Female, 42, gastric crises; had had a posterior rhizotomy done some years before. Operation May 15th, 1924; retention of urine one week; pain relieved. Seen in 1928 when she was beginning to have pain again.

16. Male, 40, gastric and "abdominal" crises. Operation Jan. 3rd, 1927; no paresis or retention; complete relief but some girdle pain. In September, 1928, again had attacks of abdominal pain which he said were as bad as they were before the operation.

17. Male, 55, lightning pains. Operation July 4th; acute mental disease with delusions and hallucinations; July 22nd mental symptoms disappeared; up and about; left hospital August 15th, 1927, with no lightning pains but girdle pain. October, 1928, still no pain except girdle pain for which he takes pyramidon.

Conclusions.

Section of the anterolateral column of the cord is an operation that may safely be undertaken for the relief of pain. Two out of 17 patients died as a result of the operation. In 15 cases a measure of relief was obtained that justified the operation. In none of the surviving cases was there any permanent ill-effect from the operation. In patients with inoperable carcinoma the relief obtained was not always complete, but such as it was it lasted as long as the patients lived. In patients with tabes dorsalis the immediate relief is good, but there is a tendency for the pain to recur a year or more after the operation.

The spinal cords of the fatal cases and of nearly all those patients who have since died of their disease were obtained and are being studied by serial sections, and it is proposed to publish an account of the findings later together with notes of the sensory changes produced by the operation.

I am indebted to Dr. C. P. Symonds, who first called my attention to the possibilities of the operation; to Dr. Perdrau, who gave me many demonstrations on his excellent collection of pathological spinal cords, and to Sir Charters Symonds for his constant encouragement and valuable suggestions.

ACTIVE IMMUNISATION AND DIPHTHERIA.

By PERCIVAL M. MAY, M.R.C.S. Eng.,
SURGEON-CAPTAIN R.N. (RETIRED); MEDICAL OFFICER, GREENWICH HOSPITAL SCHOOL;
AND
S. F. DUDLEY, O.B.E., M.D., M.R.C.P. Lond.,
SURGEON-COMMANDER R.N.; PROFESSOR OF PATHOLOGY, ROYAL NAVAL COLLEGE, GREENWICH.

It rarely happens, when an assumed prophylactic measure is followed by a diminution in the incidence of an infection which it was designed to prevent, that there can be any certainty whether the subsequent result was favourable because of, or in spite of, the antecedent procedure.

In the sequence of events to be described, there seems to be a high degree of probability that the disappearance of clinical diphtheria from an institution was a direct result of the artificial production of active immunity among its inhabitants. For this reason, though it would have been preferable to have waited another year in order to strengthen the evidence, we decided to publish this preliminary note at once, in the hope of encouraging any medical officer who might be hesitating to try active immunisation as a preventive measure for diphtheria.

During the years 1919 to 1927 inclusive, over 400 cases of diphtheria were notified from a residential school whose average population numbered 1000 boys of 11–16 years of age. All the usual methods failed to eradicate the infection. Massed throat swabbing of contacts and other samples had been a routine for ten years and, in addition to the notified cases, some hundreds of diphtheria carriers were isolated in the school infirmary until they were considered free from infection. Sometimes, from this cause alone, as many as 20 boys at a time might be kept from their training.

In January and February, 1928, the whole community was Schick-tested and about 300 of the boys who gave positive reactions were given a course of antidiphtheria inoculations (this original sample is now all Schick immune). In addition, all the Schick susceptibles, who were found among the new

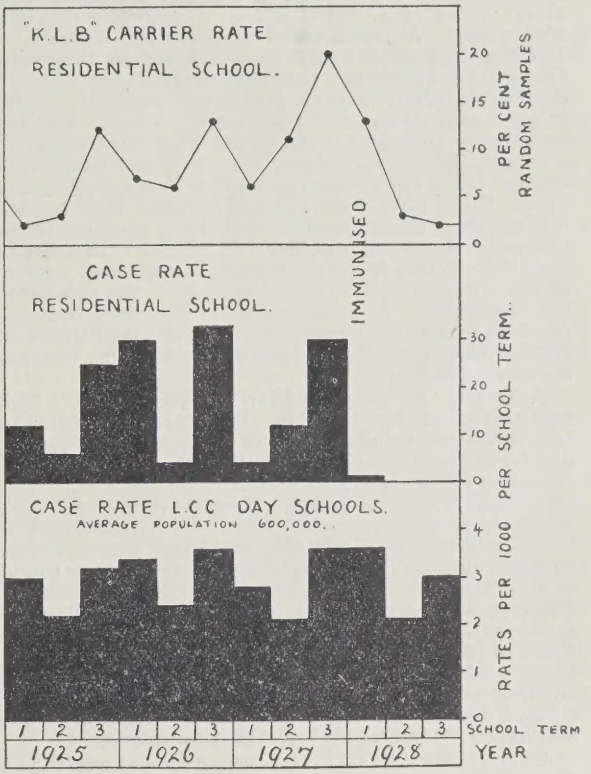
entries to the school, were also inoculated before they were allowed to mix with the more senior residents.

The incidence polygon shows that during the three years before the active immunisation of the school 43, 67, and 47 cases of diphtheria were notified. In 1928 there were only two notified cases of diphtheria. The first was reported in January before the school was protected. The other patient was a new boy who had a positive Schick test but contracted scarlet fever before he received any diphtheria prophylactic. This boy contracted diphtheria during his convalescence in the fever hospital. Therefore, since the institution of the antidiphtheria inoculations, no case of diphtheria has been notified from the school. During 1928 there were, however, four boys, the appearance of whose throats suggested a diagnosis of diphtheria. Their tonsils were covered with a thin, filmy exudate which was easily rubbed off without leaving a bleeding surface, and disappeared in all the patients within 48 hours, without the administration of diphtheria antitoxin. There was a degree or so of pyrexia but no other constitutional signs. These four boys were quite fit within a week and were not nearly as ill as the average case of follicular tonsillitis. Virulent diphtheria bacilli were isolated from only two of these cases. In the other two, repeated attempts failed to demonstrate diphtheria-like organisms in smears or cultures. It is nevertheless noteworthy that each of these four boys originally gave a Schick-positive reaction which had been rendered negative by active immunisation before the onset of symptoms. The two cases with positive throat swabs were not notified as diphtheria because, in our opinion, they were only carriers suffering from a secondary bacterial infection. But it is possible that they may have had "local" diphtheria such as has been recently discussed by Harries,[1] Neale,[2] and O'Brien, Okell, and Parish,[3] and is said to occur on rare occasions in Schick-negative reactors. These suspicious-looking throats, apart from their academic interest, illustrate two points of great practical importance. First, if a subject who is *known to have a Schick-negative reaction* has a sore-throat which suggests, but is not definitely, clinical diphtheria, there is no need for anxiety or diphtheria antitoxin. Because a case with a typical diphtheritic throat and definite toxæmia has yet to be reported in conjunction with that amount of circulatory antitoxin which is required to inhibit a properly performed Schick reaction. (One of us (S. F. D.) has discussed diphtheria in Schick-negative reactors elsewhere.[4])

Secondly, figures have been published which give the incidence of diphtheria notifications in the inoculated and unprotected members of a population. These statistics, in some cases, have not favoured the protected group as much as one would like to see. But all experience indicates that the diphtheria cases which are notified from the protected groups will, more often than not, be in the class of "local diphtheria" just described. Although anyone who has seen much "real" diphtheria would prefer to deal with 100 such "local" conditions than with half a dozen toxæmic or paralytic cases, yet one case with "local" diphtheria swells the notification returns among the protected to exactly the same extent as a fatal infection increases the incidence among the uninoculated. Even suppose the only effect of prophylactic inoculations were to increase "local" at the expense of ordinary diphtheria, without causing any reduction in the notification returns, the procedure is well worth while. Such a result would be analogous to the replacement of small-pox (variola major) by alastrim (variola minor).

The active immunisation of this school was followed by another phenomenon, which, since the difference between a case and a contact-carrier is only one of degree, was expected. Throughout 1928 random samples of 200 or more boys were swabbed at about monthly intervals in order to watch the diphtheria carrier rate. The percentage of "K.L.B. positive" examinations declined from 15 per cent. in January to 2 per cent. in December, as is seen in the diagram. For the first time in ten years, whenever the number of bacteriological examinations was large enough to be significant, the carrier incidence during the last third of the year was lowest instead of highest. This observation suggests that, provided a community is made completely Schick immune, carrier, as well as symptomatic, infections will tend to disappear.

The sequence of events in this school support the following hypothesis. Active immunisation with a diphtheria antigen tends to replace severe diphtheria



Active immunisation against diphtheria followed by a decline in the number of carriers and the obliteration of all case morbidity. (Note: Scale of L.C.C. is ten times that of residential school.)

with "local" and carrier infections, and ultimately the diphtheria bacillus, finding itself unadapted to existence in an immune herd, becomes extinct in such an environment.

Thus, in this residential school an endemicity of diphtheria equivalent to 5 per cent. per annum dropped suddenly to zero after the inoculation of the Schick susceptible members with a diphtheria prophylactic. It is important to try to decide if the above fact was in spite of, or because of, the alleged preventive measure. The arguments that could be urged in favour of coincidence as against causation are:—

1. The disappearance of symptomatic diphtheria might have been part of a general natural phenomenon, since the histogram of the morbidity from diphtheria in the London County Council schools appears to be on the decline. The decline, however, does not seem great enough to be a likely explanation of the *complete* disappearance of diphtheria from a large London institution.

2. Between 1919 and 1927 (according to the residential school records) there were three school terms out of 27 in which no case of diphtheria was notified, and during six terms (two years), previous to a big outbreak in 1921, only eight cases are recorded. Therefore, the absence of diphtheria from this school

has been seen on occasions before the institution of prophylactic inoculation. But on no occasion, for ten years previous to 1928, has diphtheria been absent for two consecutive terms; and during the two years of comparative freedom, following an epidemic in 1919, the carrier rate, based on over 1000 examinations, was less than 1 per cent., which was lower than any subsequently recorded rates where the sample contained more than 100 boys. The low incidence between 1919 and 1921 was probably due to a real scarcity of diphtheria bacilli in the environment. In 1928 over 3000 throat swabs showed 7 per cent. of carriers compared with about 5 per cent. (8000 swabs) during the previous nine years. About a third of some 200 cultures of *Bacillus diphtheriæ* which were isolated in 1928 were toxigenic; therefore, the carrier rate for virulent diphtheria bacilli averaged about 2 per cent., which implies that about 300 boys were probably infected as carriers throughout the year. Moreover, about 60 virulent diphtheria carriers were actually discovered during 1928, and, contrary to the routine of former years, these boys were neither isolated nor treated (unless their throat or nose called for surgical interference). Ignoring carriers of virulent diphtheria bacilli has been justified, because no notified case of diphtheria has arisen in the school since the procedure was instituted. It seems unlikely, therefore, that the freedom of the boys from symptomatic diphtheria in 1928 can be attributed to lack of contact with virulent diphtheria bacilli.

3. It may be possible that the confidence, which was produced by faith in the preventive value of the inoculations, changed the personal equation in diagnosis from one of overcaution to a subconscious refusal to diagnose diphtheria. This possibility was continually borne in mind. Nearly every sore-throat which was reported after active immunisation had been instituted was critically examined and swabbed to the number of 71. Diphtheria bacilli were found in four instances, a rate which was not significantly different to that prevailing among apparently healthy unselected boys during the period in which these cases of sore-throat were recorded. We do not think that, under any circumstances, these sore-throats could have been considered to include any cases of clinical diphtheria, with the possible exception of the suspicious "local cases" referred to above.

4. The rapid decline in the carrier rate, shown in the diagram, may have been a natural phenomenon, unconnected with the prophylactic inoculations and secondary to some unknown factor which was causing the diphtheria bacillus to find the infection of fresh hosts, either as cases or carriers, difficult in this environment. In spite of much cogitation, no alteration in the school conditions other than the absence of Schick susceptibles could be discovered or imagined to account for the departure of the diphtheria bacillary herd from its usual behaviour towards the human herd.

5. Perhaps the most telling argument in favour of coincidence, rather than active immunity, accounting for the absence of notified diphtheria in 1928, is the paradoxical fact that none of the Schick-positive new entries to the school contracted diphtheria before their reactions were made negative. During the year following the institution of antidiphtheria injections, 183 boys who had positive reactions joined the school, and it was fully expected that a few cases of clinical diphtheria would appear among them. The new entries to this establishment are always at first segregated in a different building for three weeks or a month before going over to the main school. During this period they received their first dose of diphtheria prophylactic. Their freedom from clinical diphtheria might be explained by supposing that those inoculated boys, in whom circulatory antitoxin had not appeared in sufficient quantity to neutralise a dose of Schick toxin, had acquired a rise in their "basal immunity" during the week or two that elapsed before they mixed with the boys already in the school. If this surmise was correct, it indicates that if active immunisation is undertaken during the course of an epidemic it may be expected to produce almost immediately a favourable effect on the severity of symptoms and incidence of all types of infection, even before there has been time for Schick-positive reactions to become negative.

The most important fact in favour of the view that the disappearance of typical clinical diphtheria was directly caused by the injections of a diphtheria antigen is, that whereas the ratio of Schick-negative reactors to Schick-positive reactors averaged 3 : 1 for five years previous to the inoculation of the school, when every allowance is made for the time required to immunise the susceptible new entries, this ratio or "herd immunity index" now averages over 30 to 1.

It seems fair to conclude from a careful sifting of all the facts that the freedom from diphtheria in an institution which had had an average morbidity of 4 per cent. for the previous ten years was a direct result of the artificial production of an active immunity, and not merely *post hoc ergo propter hoc.*

Since the chief purpose of this preliminary note is to encourage others, two other facts are relevant: (*a*) For the original Schick and prophylactic injections the permission of 1004 parents and guardians was requested. Only seven refused to allow their boys to be protected against diphtheria. (*b*) There has not been a reaction following nearly a thousand prophylactic injections that has necessitated a single boy standing off duty for a day.

We must express our thanks to Dr. R. A. O'Brien, who supplied the diphtheria prophylactics, and to Surgeon-Commander H. B. Parker, who coöperated in much of the technical work referred to in this note.

INDUCTION OF ABORTION FROM THE PSYCHIATRIC STANDPOINT.*

BY BERNARD HART, M.D., F.R.C.P. LOND.,
PHYSICIAN IN PSYCHOLOGICAL MEDICINE, UNIVERSITY COLLEGE HOSPITAL, AND NATIONAL HOSPITAL, QUEEN-SQUARE.

THE disorders with which the psychiatrist has to deal fall into two great groups, the psychoses or definite insanities, and the psychoneuroses or so-called "functional nervous disorders." These two groups require independent consideration with regard to the induction of abortion.

Psychoses.

The psychoses occurring in association with pregnancy may be dealt with under three headings: (1) cases where a psychosis develops after the occurrence of pregnancy; (2) cases where pregnancy arises in the course of a pre-existing psychosis; and (3) recurrent psychoses.

Cases where psychosis develops after occurrence of pregnancy.—It was formerly held that the psychoses developing during pregnancy and the puerperium were definite entities, constituting special forms of mental disorder. This view has been generally abandoned, and it is now realised that the disorders in question belong to types met with under other circumstances than pregnancy. These types fall into two groups. Firstly, diseases such as dementia præcox or manic-depressive insanity may manifest themselves during pregnancy. In these cases the pregnancy may play a part as an exciting factor determining the precise moment of the attack, but cannot, of course, be regarded as an essential cause. So far as this group is concerned it is clear that the pregnancy is only a

* Being a contribution to a discussion at the Medical Society of London on March 25th.

circumstance of minor importance, and that its removal is not likely materially to affect the course of the disorder. Clinical experience bears this out, and abortion is not therefore justifiable here from a psychiatric standpoint. Obstetric difficulties due to an exceptionally acute mental condition might a priori have to be considered, but I believe that in practice these have not been found to be very great.

The second group comprises cases of "exhaustion psychosis," a form of disorder in which toxic factors or emotional strains apparently play a decisive part. In this group the pregnancy is a factor of definite causal importance, and it might be thought that its removal would therefore clearly tend towards mental recovery. Clinical experience, however, does not support this supposition, and it has generally been noted that the induction of abortion does not materially affect the course of the disorder. On the whole, cases arising early in pregnancy tend to recover before confinement, those arising later tend to recover some time after confinement, and the duration and severity of the illness is not notably different whether abortion is carried out or not. Hence psychiatrists are increasingly reluctant to recommend termination of the pregnancy in these cases for purely psychiatric reasons, though, of course, in any individual case reasons of a non-psychiatric order may arise. Dr. Percy Smith has published an interesting series of cases from which these conclusions receive considerable support.[1] In this connexion it has been pointed out that the operation of abortion may itself be a factor tending to accentuate an exhaustion psychosis, just as does a confinement at full term, and therefore we may be adding a factor to the causes of the mental illness rather than subtracting one.

A third group should perhaps be placed here comprising those cases developing early in pregnancy where the symptoms are of a melancholic type with marked anxiety, but where there is no definite evidence of the existence of a schizophrenic or manic-depressive psychosis. The cases included here, however, seem to be merely the more extreme examples of anxiety conditions which in their milder forms belong to the psychoneuroses, and will therefore be dealt with subsequently under this latter heading.

Pregnancy arising in course of pre-existing psychosis.—The considerations mentioned in the preceding section apply with redoubled force here, and in this group it may be laid down that abortion for purely psychiatric reasons is rarely justifiable.

Recurrent psychoses.—Those cases are included here in which one or more former attacks of insanity have occurred, although at the time of the pregnancy no such attack has manifested itself. Two subgroups have to be distinguished, the first comprising those cases where the former attacks had no relation to a pregnancy, and the second those cases where a psychosis has developed in association with a former pregnancy or puerperium.

So far as the first subgroup is concerned each case must be decided on its merits. Where several attacks have occurred, generally in association with some factor of stress, then abortion would seem to be justifiable on the ground that a continuing pregnancy is likely to act as such a stress. Even here, however, experience shows that many such patients go through a pregnancy without any mental breakdown. In the second subgroup, where former attacks have occurred either during pregnancy or in the puerperium, the indications for abortion are weighty, and become greater where two or more previous pregnancies have been accompanied by mental breakdowns.

Psychoneuroses.

In considering the psychoneuroses we enter upon a much more difficult field, and one where there is no place for rigid principles and opinion.

We have to do with a sphere of disorder where psychological factors play a predominant part in causation, and amongst such factors the anxieties and fears which may centre round a pregnancy may be of fundamental importance. We may clear the ground by saying that where there is a pre-existing psychoneurosis, and where the fact of pregnancy is not itself a cause of any anxiety or fear, then there is no indication for abortion. There does not seem to be any clear evidence that pregnancy brings with it special dangers in a psychoneurotic, except in so far as its existence is a source of psychological distress. In other words, pregnancy as a merely physical phenomena is not of consequence in a psychoneurotic.

Excluding these cases, however, there are a great number in which the pregnancy itself gives rise to acute anxieties and conflicts. A multiplicity of psychological factors may be involved therein, conflicts with regard to sex, the attitude to marriage, and the relation to the husband, factors perhaps reaching far back in the history of the patient, but the pregnancy constitutes a nodal point in which all these factors are condensed, and for practical purposes it may be regarded as the immediate central factor in the production of the psychoneurotic symptoms. Here there can be no doubt that the induction of abortion will relieve the symptoms, and perhaps avert the development of a serious nervous breakdown. In cases where such a situation is obviously present it would seem that abortion is clearly justifiable, but the decision must rest on a question of degree, because we have to deal here with a series of cases ranging from the grave conditions just depicted to conditions where the patient is merely emotionally upset because an unwanted pregnancy has appeared, and nowhere in this series can a well-marked dividing line be drawn. It is pre-eminently in this series that each case has to be decided upon its merits, and it cannot be denied that the grounds are so uncertain, and there is so much room for individual differences of opinion, that there may be a risk of the practitioner being unconsciously swayed by the pressure put upon him by the patient or her relatives.

In this series of cases there is a group which stretches across the gap between the psychoneuroses and the psychoses, the group where severe anxiety conditions pass over into clinical pictures of a definitely melancholic type. Here the factor which dominates the problem at issue is the risk of suicide. There are certain cases in which the woman will remark that she would rather die than go through with the pregnancy, and where the remark may safely be neglected; but there are other cases in which the patient's terror of the ordeal before her is so potent that suicide is not an unlikely contingency. In such cases it is generally agreed that the pregnancy should be terminated, but here again it is not easy to drawn a definite line.

It has been laid down that the practitioner is "not entitled to let anything weigh with him except the health of his patient—her medical welfare as distinct from her social or economic welfare."[2] This dictum is obviously true in the present state of the law, but its application in the cases we have just considered is by no means easy. In the sphere of the psychoneuroses, where psychological factors are predominant causes of illness, social and economic circumstances may react in all sorts of ways upon the mental health, and though we may endeavour to limit our attention to the latter, the former are ranged behind it. We may decline to take them into account directly, but indirectly they may force themselves upon us.

It can only be concluded that in this group no general rule can be laid down. The attention of the psychiatrist must be focused upon the central problem of the probable effect of allowing the pregnancy to continue upon the mental and nervous health of the patient, but factors of many kinds have to be considered in determining this probable effect, and the final decision must depend upon the estimation of the force and interactions of all these factors.

Clinical and Laboratory Notes.

VISCID BLOOD AND HYPERGLYCÆMIA IN DIABETES MELLITUS.

By Alex. Mills Kennedy, M.D. Glasg., M.R.C.P. Lond.,
PROFESSOR OF MEDICINE AND DIRECTOR OF THE MEDICAL UNIT, WELSH NATIONAL SCHOOL OF MEDICINE.

THE following brief account records the salient features of an unusual blood in a case of diabetes which recently came under my observation.

A woman of 62 years, weighing 10st. 6 lb., had been suffering from diabetes for about two and a quarter years before coming into hospital under my care. Her chief symptoms had been great thirst, polyuria, and loss of weight, and her doctor had prescribed a diet to which, however, she paid little attention. Increasing weakness and backache obliged her to take to bed about 11 weeks before admission to hospital. Her tongue and mouth were very dry and she would drink about 20 glasses of water daily. Her bowels had been very constipated and headache troubled her for the three to four weeks preceding admission.

On admission to hospital she was quite conscious, but slightly drowsy, and complained of thirst. She could answer questions and gave the history of her illness, although she was rather slow mentally and inclined to wander off the point. Her skin was dry and loose, temperature subnormal, pulse 112, and respirations 24. Her pupils were contracted—the right more so than left—but both reacted normally to light and on accommodation. The knee- and ankle-jerks were absent. Her lips were slightly cyanosed and she seemed just a little short of breath, but became more comfortable when propped up in bed by pillows. There was, however, no suggestion of "air-hunger," but her breath smelt of acetone. Her *urine* contained 6 per cent. of glucose and acetone and diacetic acid—both the Rothera and ferric chloride tests giving immediate strong reactions.

Blood was then withdrawn from the median basilic vein at the bend of the elbow by means of a needle and 10 c.cm. syringe. The blood did not flow spontaneously but only entered the syringe with difficulty on suction. It was very thick and very dark, its colour and consistency being almost the same as treacle. Examination by the method of Folin and Wu showed sugar present to the extent of 754 mg. per 100 c.cm.

She was given abundant fluid by the mouth, and, later, per rectum, and while waiting for the result of the blood analysis it was noticed that her drowsiness was increasing until she could only be roused with difficulty. Consequently she was given 40 units of insulin hypodermically and 20 g. of glucose by the mouth. Some three and a quarter hours later (about midnight) she was still very drowsy and stuporose, and, as the urine was found to contain acetone and diacetic acid and a large quantity of sugar, she was given another 40 units of insulin hypodermically and 20 g. of glucose by the mouth.

At 7 o'clock the next morning her general condition was much about the same and urine examination revealed 5 per cent. glucose, and immediate strong reactions were obtained with Rothera and ferric chloride tests. 40 units of insulin were given hypodermically along with 20 g. of glucose by the mouth. At 9 A.M. the urine sugar was 4·8 per cent. and the Rothera and ferric chloride tests still strongly positive. At 11 A.M. the blood-sugar was found to be normal—viz., 110 mg. per 100 c.cm.—and the blood obtained from venepuncture normal in colour and consistency and flowed easily.

The patient was now rather better but still drowsy, and through a misunderstanding, before the result of the blood-sugar examination was known, she was given another 40 units of insulin and 20 g. of glucose. She vomited the glucose, however, and at 11.30 A.M., the result of the blood-sugar examination being known, she was given 50 g. of glucose per rectum. At 12 noon the urine contained 0·2 per cent. of sugar and gave a slow weak reaction with the Rothera test and a negative ferric chloride test. At 12.30 P.M. the blood-sugar had fallen to 40 mg. per 100 c.cm., and later some hypoglycæmic symptoms appeared in the shape of flushing and sweating, but no convulsions. These were counteracted by giving glucose by the mouth and per rectum and adrenalin hypodermically.

At 4 P.M. the blood-sugar had returned to normal—120 mg. per 100 c.cm.—and a little later very marked improvement in the patient's general condition set in. At 8.30 P.M. the urine was quite free from sugar, acetone, and diacetic acid, and the patient was very well indeed. Subsequent progress was uneventful and satisfactory, but insulin treatment had to be continued (about 45 units per day).

The principal feature of the case was the condition of the blood when the patient first came under observation. Its sugar-content (754 mg. per 100 c.cm.) was exceptionally high, and this was associated with a dark, almost black, and thick, treacly condition of the blood. The patient was inclined to be drowsy at the time, but not in actual coma, and she never had "air-hunger." One would be inclined to think that a thick blood such as this must be prone to stagnation in the capillary circulation and might be responsible for some of the increasing drowsiness and torpor present.

The lips were slightly cyanosed, but there was, however, no cyanosis of the extremities, engorged veins, or other external evidence of circulatory stasis. The very quick change of the blood to normal on giving abundant fluid and insulin is another noteworthy feature.

A CASE OF INFECTION WITH *BACILLUS MORBIFICANS BOVIS* (BASENAU).

By S. H. Warren, M.R.C.S. Eng., D.P.H. Lond.,
DIRECTOR, PUBLIC HEALTH LABORATORY, UNIVERSITY OF DURHAM COLLEGE OF MEDICINE, NEWCASTLE-UPON-TYNE.

ALL diseases caused in human beings by pathogenic organisms derived from the domestic cow are of great public health importance. The organism in this case, *B. morbificans bovis* Basenau, is one which only rarely causes infection in human beings and usually gives rise to a sudden attack of gastro-enteritis, now often termed "food poisoning." Very few references to this organism are to be found in the literature. It was first described by Basenau [1] in 1893, and was isolated from the internal organs of a cow which had been slaughtered while suffering from puerperal metritis. He noted its similarity to an organism found in another animal, the meat of which had caused an extensive outbreak of gastro-enteritis. He examined and compared this organism with others which had caused food poisoning, including *B. enteritidis* Gaertner, and concluded that its culture and pathogenicity were sufficient to distinguish it as a definite species which he named *B. morbificans bovis*.

Savage,[2] in his investigation into the presence of the Gaertner group of organisms in the animal intestine, examined the cultural and biochemical reactions of this organism. One point he noted was that, while most of the many organisms he examined were able to grow on a medium containing 0·05 per cent. of malachite green, dulcite broth, *B. morbificans bovis* failed to do so. The organism has been recognised as a distinct type of the salmonella group, and its antigenic composition has been studied in detail by Bruce White.[3] His analysis places it as a distinct diphasic type of salmonella, its specific phase being quite distinct, and its group phase showing its relationship to *B. suipestifer*, types Reading and Thompson, members of the salmonella group. Sladden and Scott [4] reported an outbreak of food poisoning in Swansea in June, 1926, probably due to pressed beef. They isolated this organism from the fæces of four of the patients attacked. Detailed examinations of the strains isolated were carried out, including analysis of the group antigen, and they confirmed the opinion of Bruce White as to the position of this organism in the salmonella group. A brief history of a recent case will show some points of interest. The onset was fairly sudden, but not of the usual food-poisoning type, and the illness was more of the

nature of a gastro-enteritis with fever. At one time the disease suggested typhoid, and later it was thought to be possibly bacillary dysentery.

The patient, a girl aged 17 years, had been working for three weeks for two or three days a week as a daily girl on a farm. No information is obtainable as to the precise source of the infection. She was taken ill on July 14th with diarrhœa and abdominal pains, and when first seen by a doctor on July 16th was in bed with a temperature of 101° F. On August 1st she was still very ill, the temperature having continued between 100° and 102°, and was having at least five motions in the 24 hours. The case was notified as a doubtful enteric on August 10th, and blood then taken was found to give no agglutination with emulsions of typhoid, paratyphoid A, and paratyphoid B bacilli. On August 14th the patient was becoming very weak, with rapid pulse and numerous loose motions, one of which contained some blood. This specimen was sent to the laboratory for examination, and in view of the negative agglutination reaction was thought that the case might possibly be one of bacillary dysentery.

After August 17th she began to improve, the temperature and pulse gradually falling to normal during the next few days. After August 23rd she was able to take more food and became convalescent, but was very emaciated. She finally made a complete recovery.

The sample of fæces arriving at the laboratory on August 16th was examined by direct plating on McConkey plates, and by the brilliant green enrichment method. Direct plates showed no non-lactose fermenting colonies, but the plates planted after brilliant green enrichment showed a few such colonies. These colonies (522) were of a motile Gram-negative bacillus which gave the sugar reaction of the salmonella group—viz., acid and gas in glucose, mannite and dulcite; no change in saccharose and lactose and slight acidity followed by alkalinity of litmus milk, and no indol (after 14 days' incubation). Gelatin was not liquefied. Broth cultures of this organism failed to agglutinate with any one of the following sera: *B. paratyphosus* B and C, *B. enteritidis* Gaertner, *B. aertrycke* Mutton and Newport, but it was agglutinated to 1 in 50 by the serum of the patient taken on August 23rd, which was again negative to typhoid and paratyphoid A and B. The organism was subcultured in broth for four days and the reaction repeated with the same result.

The following cultures and serum having been obtained from Dr. W. M. Scott, (1) *B. morb. bovis*, specific; (2) *B. morb. bovis*, Furseman specific; (3) serum *B. morb. bovis*, group and specific, it was then found that the patient's blood taken on Sept. 3rd gave the following reactions:—

—	25	50	125	250	500	0 C
Own organisms No. 522 ..	+	+	+	—	—	—
B. morb. bovis F.	+	+	+	—	—	—
B. morb. bovis	+	—	—	—	—	—

C = Control.

The titre of the serum (*B. morb. bovis*, group and specific) was found to be practically identical to the three organisms, and was as follows:—

—	Thousands.									0 C
	0·25	0·50	1·25	2·5	5	10	25	50	100	
522.. ..	+	+	+	+	+	+	±	—	—	—
B.M.B. F.	+	+	+	+	+	+	Tr.	—	—	—
B.M.B. ..	+	+	+	+	+	+	Tr.	—	—	—

In addition, after saturation of this serum with the isolated culture 522, all the agglutinins to both cultures of *B. morb. bovis* were removed (from dilution of 1 in 250) as well as for the culture 522 itself. It was further noted that the organism 522 rapidly fermented inosite (24 hours) with the production of acid, but only very little gas, the stock cultures giving similar results but with more gas-production. Arabinose was also fermented with the production of acid and gas in 24 hours, and lead acetate broth was blackened. It is of interest to note that, as we have previously found with other members of the salmonella group, brilliant green enrichment (1 in 200,000) facilitated the isolation of the organisms.

I wish to thank Dr. J. G. Walker, medical officer of health for Lanchester, Co. Durham, for the history and specimens, and Dr. W. M. Scott, of the Ministry of Health, for cultures and serum of *B. morbificans bovis*.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

COMBINED SECTIONS OF UROLOGY, PATHOLOGY AND THERAPEUTICS.

A JOINT meeting of these Sections was held on March 21st, Mr. SWIFT JOLY, President of the Section of Urology, in the chair. Dr. W. LANGDON BROWN opened a discussion on

URINARY ANTISEPTICS.

He said that it would be convenient if the term "bacilluria" were reserved for the passage of bacteria through the renal system without inflammatory reaction, which was constantly occurring and called for no treatment. When pus accompanied bacteria in the urine some inflammatory condition had been set up and needed treatment. Bacilluria might be turned into cystitis by any obstruction to the flow; by an organic lesion of the nervous system; by trauma, such as a blow over the kidney in football, and by focal sepsis. In the last-named the best treatment was to deal with the source of the trouble. The large intestine provided a source of extended sepsis, especially if there were some obstruction such as diverticulitis, and the relation of the hepatic flexure to the right kidney made infection by this route easy. In these cases intestinal antiseptics, kaolin, and Plombières douches were as important as treatment of the urinary tract. The only organisms of practical importance for renal infections were the *Bacillus coli*, *B. proteus*, streptococci, staphylococci, gonococci, and the tubercle bacillus. Ascending infection was more common in women and babies; the colon bacillus was said to inhabit the vulva of 50 per cent. of normal women. It was rare in men, but in either sex might arise from the peri-urethral lymphatics. There was an enormous preponderance of *B. coli* infections, but it was important to guard against concluding that a case was one of simple *B. coli* infection because only coliform bacilli were found in the urine; a tuberculous infection or a new growth might be concealed behind this. As a general rule a case that proved very resistant to treatment, in that signs and symptoms persisted, should not be regarded as a simple infection. There was some doubt whether the "coliform" infection was really the ordinary *B. coli communis* or some organism like it, but, as it had been shown that the bacillus in the urine might be strongly hæmolytic at the height of the infection and gradually return to a form typical of *B. coli communis*, it was hard to resist the conclusion that the ordinary bacillus could produce pathogenic effects when outside its normal environment.

Antiseptics in Common Use.

Many substances had been found successful in vitro that were not so good clinically; the bladder, unfortunately, was not lined with glass. The benefits of intravenous administration were not solely due to the germicidal action of the drug. H. H. Dale thought that they were partly due to modification of virulence or lowering of the resistance of the invader to the natural defences, partly to the formation in the body of some substance directly antagonistic to the germ, and partly to the formation of a depôt from which a curative substance was slowly distilled. Mercurochrome and gentian violet were the substances chiefly used; at the Mayo clinic the former was given in doses of 4 mg. per kg. of body-weight in 1 per cent. solution, but even this dose occasionally led to rigors, vomiting, and diarrhœa, and should only be used as a last resort. Helmholz and Field maintained that hexamine was definitely superior; Braasch and Bumpus claimed good results from doses of 5 c.cm. of a 10 per cent. solution. It was extraordinary how little general agreement there was as

to the efficacy of the various drugs given orally for urinary antisepsis. *Hexamine* was rapidly absorbed and appeared in the urine, bile, and cerebro-spinal fluid about 20 minutes after administration. It was said to form formaldehyde in an acid urine, but if so there seemed no reason why it did not also form formaldehyde in the presence of the gastric hydrochloric acid. At any rate, the amount liberated was small, and some authorities said that the patient found the drug intolerable just as soon as the formaldehyde began to appear. No doubt hexamine could be very irritating and cause hæmaturia. Dr. Langdon Brown had found it less irritating when given with methylene-blue; the combination diminished subjective symptoms and reduced the amount of pus and organisms, but the infection persisted. *Acid sodium phosphate* had been recommended by R. Hutchison as the natural acidifying agent; only half the dose was absorbed, the rest passing out through the bowel. This drug could prevent the post-prandial alkaline tide and the slow ammoniacal decomposition resulting from bacterial infection, though it could not correct a strongly ammoniacal urine. It was usually given with hexamine. Blaustein held that calcium and ammonium *chlorides* were stronger acidifiers in an alkaline cystitis; he gave ammonium chloride in doses of grs. 15, t.d.s., up to grs. 30 every three hours. *Benzoic acid* was synthesised in the kidney with glycin and excreted as hippuric acid which, according to Stockman, took up so much alkali to be excreted as hippurate that more phosphate was able to take the form of acid phosphate. The ammonia split off from urea by ammoniacal decomposition combined with this acid salt and the urine became clear. Stockman preferred to give *ammonium hippurate*, as a smaller dose of this was effective. The latest drug was *hexyl resorcinol;* this was inactive when given with sodium bicarbonate—according to Leonard and Frobisher because of alteration of surface tension, so that the drug could not enter the crevices of the mucosa. In any case most of the drug was conjugated and only small amounts excreted in an active form. Great claims were made for it which, if justified, were some set-off for its prohibitive cost. D. A. Brown had said that the chief feature was relief of bladder irritations; he gave it in 0·15 g. capsules, 9 to 12 a day for 7 to 30 days in acute cases and 30 to 60 days in chronic cases. Half the patients had suffered from gastro-intestinal disturbance. Stockman agreed that it reduced the number of organisms and the symptoms, but did not find it effective in eradicating the infection. *Salicylic acid* was never found free in the urine, being excreted as inert salicyluric acid. Salol appeared as sodium salicylurate and sulphocarbolate. Stockman was unable to understand the reputation of salol as a urinary antiseptic; it might perhaps be due to its action as an intestinal antiseptic. *Boric acid*, given in five-grain doses, was a weak antiseptic in both acid and alkaline urine. It was best given in keratin capsules together with salol, and seemed to relieve the symptoms of chronic *B. coli* infection. *Acriflavine*, a grain and a half three times a day in keratin capsule, had been recommended by Browning and Gulbransen. The difficulty was to get the keratin the right thickness; if the drug was absorbed successfully it gave the urine a deep yellow colour. *Copaiba* and *sandalwood oil* had been used, and sometimes relieved the symptoms; they were most useful in gonococcal cystitis.

Change of Reaction, Vaccines, Lavage.

One of the most important methods of treatment was to change the reaction of the urine, altering the habitat which suited the microbe in question. It was easier to make an acid urine alkaline than vice versa. The patient found alkalis more tolerable in acute infections. Potassium citrate and sodium bicarbonate on the one hand, and ammonium and calcium chloride and acid sodium phosphate on the other, were used to make the change; it might be necessary to change the reaction more than once. We needed to know a great deal more about the urine reaction; some urines became sterile by themselves if obstruction were removed. Large quantities of water were useful, but should not, of course, be prescribed while an attempt was being made to sterilise the urine by antiseptics. Vaccines never made the urine sterile, but might relieve a toxæmia; they were more successful in coliform than in coccal infections. Dr. Langdon Brown said he had sometimes been greatly impressed by the effects of lavage, application of silver nitrate, and irrigation of the renal pelvis. Any case which did not respond rapidly to medical measures should be examined by the cystoscope.

A Pathological Experiment.

Dr. CUTHBERT DUKES described an investigation into the value of urinary antiseptics in 28 cases of cystitis produced by a tie-in catheter in patients whose rectum had been excised for carcinoma. The cystitis had appeared invariably in four or five days so long as the catheter had been stopped with a wooden peg, the infection arising at the junction of peg and catheter and spreading up the column of urine in the catheter. There had been no symptoms except irritability of the bladder; in the early stages the organisms were pyogenic cocci, usually staphylococci, but in the later stages coliform organisms had predominated on agar culture, though the cocci remained predominant in broth. Mild uncomplicated cases recovered without treatment in four to six weeks. The effects of the antiseptics had been judged by clinical observation, by daily quantitative estimations of pus in the urine, and by repeated bacteriological examinations. The amount of pus had been found to be an expression of the nature and not of the severity of the infection. Of seven cases treated with hexyl resorcinol, one recovered in 30 days and another in 25 days; the remaining five derived no benefit. Of 12 cases treated with hexamine only one recovered more rapidly than was expected. Most of the patients complained of the discomfort of the treatment. In four cases treated with methylene-blue there was no sign of any benefit. The best results were obtained in five cases treated with alkalis, which made the patient more comfortable and might perhaps shorten the natural duration. At present the best treatment for catheter cystitis was to give non-stimulating diet with large quantities of water and to keep the urine faintly alkaline to litmus. A glass of water should be drunk every hour; no medicine was required at all if the urine were already alkaline.

Discussion.

Dr. PHILIP HAMILL pointed out that few coccal cases fell to the lot of the ordinary physician, who generally found that he could not push hexamine and acid medication because of the pain. He had been satisfied that cases cleared up just as quickly on water alone. The great value of alkaline treatment was that it rendered micturition painless, so that the patient could be persuaded to take fluids. Methylene-blue made the patient more comfortable, and so did flavine and caprokol, but the former did not reduce the pus. Dr. Hamill then described some experiments on the cultivation of organisms with the urine of a normal subject who had taken hexyl resorcinol. They showed that the urine became very highly bactericidal to *Staphylococcus aureus*, but had no antiseptic effect on *B. coli* until it became fairly alkaline.

Mr. F. A. JEANS said that in his experience hexamine made tuberculous kidneys worse. It was only irritating if there were no albumin to counteract it; if the pelvis were full of pus, formaldehyde caused no discomfort. Empirically it was a good thing to alter the reaction of the urine, whichever it was.

Dr. L. P. GARROD said that colon bacilli grew very much faster in alkaline than in acid urine, and that this was not due to nutrient substances present at the time of the alkaline tide after meals. To interfere with the growth of *B. coli* in urine the urine must

be made strongly acid, but this caused the patient too much discomfort. The growth of organisms in the sterile urine of a normal person who had taken an antiseptic drug would give an accurate idea of the value of the drug in question.

Mr. F. E. FEILDEN said that few conditions were more difficult to treat than uncomplicated *B. coli* infection; in his experience hexamine, acid sodium phosphate and flavine were the best drugs. Hexamine accentuated the symptoms in many cases, and he had been more impressed by flavine, in doses of half a grain three times a day, with an alkali. Amounts of 1 in 300,000 were enough to inhibit the growth of the gonococcus.

Dr. KINGSTON BARTON held that the easiest and most comfortable drug to give was hexamine, but the acidity of the urine must be known. It should never be given in large doses, especially at night, but in small amounts every few hours, for it passed through very quickly. The more of it that was given before noon, the more efficacious it was. Formalin must get into the gastro-intestinal tract, for many patients complained of "indigestion" when taking hexamine. This could be obviated by giving the drug before meals.

Mr. JOHN EVERIDGE said that without question hexamine was a most valuable drug, and gained additional value by being given about an hour after the acid sodium phosphate. The urologist frequently tied in a catheter, but did not get catheter-cystitis; he wondered if the infection described by Dr. Dukes was really a urethritis. Hexamine was believed to fail in pyelitis because it did not remain long enough in contact with the inflamed area; this might also apply to urethritis.

Dr. GEORGE GRAHAM thought there was no scientific evidence for the value of hexamine, which he no longer used. It was often given with an alkali or in alkaline urine, and it was the alkali that did the good.

Dr. ELIZABETH LEPPER said that experiments she had done had shown that hexamine was on the borderline of useful antiseptics. Just enough of it was dissociated in the urine to produce some effect; probably it acted on some coliform organisms and failed to touch other more resistant strains.

The PRESIDENT said that he had become very pessimistic about chronic infections of the kidney; if they persisted more than a few months they would persist indefinitely, become bilateral, and eventually kill the patient. Coccal infection with renal stone called either for primary nephrectomy or at any rate for removal of the kidney if the infection persisted a year after removal of the stone.

Dr. LANGDON BROWN, replying, said that there was, in fact, very little satisfactory pathological evidence of the efficacy of the drugs in common use, but there was a good deal of clinical evidence that the patient could be made comfortable.

Dr. DUKES, in reply, emphasised that his results must only be taken to apply to the particular form of catheter cystitis in question; he was convinced that it was a cystitis and not a urethritis. It might spread to the kidneys and cause grave complications. Though symptomless, it produced much ill-health.

SECTIONS OF DERMATOLOGY AND EPIDEMIOLOGY.

ON March 21st a joint meeting of these Sections was held, with Dr. J. M. H. MACLEOD, President of the Section of Dermatology, in the chair, to discuss the Causation, Recognition, Prevention, and Treatment of

INDUSTRIAL DERMATOSES.

The CHAIRMAN said the subject was important not only to the medical profession, but to the whole industrial world. If, as a result of the discussion, a keener interest was aroused in the problems of industrial dermatitis and methods of prevention, it would have served a very useful purpose. Celsus and Agricola referred to the dangers of ulceration of the skin from contact with corrosives. Agricola also mentioned the baneful action of a kind of "cadmia," which Mr. Hoover, President of the United States and a distinguished modern engineer, recognised as arsenical cobalt. Robert Willan was the first to describe the psoriasis palmaris of shoemakers, dermatoses in metal workers, grocers' itch, and washerwomen's eczema.

Dr. SIBYL OVERTON began by speaking of the growing importance of these dermatoses, both to the nation and the individual. Many thousand man-hours were lost annually through this form of disability, and even one attack of dermatitis might prevent a skilled worker from pursuing his trade again. In 1927 a minimum of 3000 days' work was lost on account of trade dermatitis in factories. Since the passing of the Workmen's Compensation Act in 1906 the claims on this account had largely increased. In 1908 the claims numbered 19, on account of eczematous ulceration of the skin, while in 1927 the figure had risen to 897. The number of substances being used in various manufactures had largely increased of late, as had the proportion of skin irritants so used. The most important single event in the causation of these dermatoses was injury to, or destruction or separation of, the horn cells of the epidermis. A prominent place in the ætiology was taken by alkalis; the horn cells were more tolerant of acids, in the stronger solutions, than of alkalis. In bakers' dermatitis the phosphoric acid in the sweat was said to form acid aldehyde which, in the presence of oxygen, broke down to produce formic acid. Over-lubrication of the skin by oil served to swell the number of cases. Dermatitis levied a heavy toll on engineers, perhaps because of the fine particles of metal in the oily mixtures handled. The dyeing industry and calico-printing were responsible for many cases of trade dermatitis annually. Painters acquired skin disease not from their paint, but from the turpentine and its substitutes they used to remove paint from hands and arms after work; the paraffin so used took its place among the irritative agents. She suggested that here there was scope for the work of the experienced chemist. Cotton-seed oil was a good substitute for more irritating cleansers.

As a result of inquiry into thousands of cases the conclusion reached was that most of these cases were preventable. More knowledge was needed of harmless yet effective methods of removing stains from the skin, and certainly there should be a daily removal of irritants from the surfaces concerned. The prime object was always to preserve the protective layer of horn cells. Emollients should be used before and after work. After work any irritant must be completely removed by harmless methods. An experienced observer should be allotted the task of inspecting the hands and arms of the workers with power to enforce the early treatment of minor injuries, such as cuts and burns. Dermatitis was often preceded by such small damage, and this damage was often the starting place for the more widespread skin eruption. Hands, arms, and overalls must be scrupulously cleansed on leaving work. Forearms were often rubbed over with a contaminated overall. After the Government Order of 1919 cases still continued to come up, but there was a steady diminution. In wet processes the feet and legs were often the parts first affected. Patent cleaners for boots and shoes contained ammonia, and cases of dermatosis were attributed to that, and also to the oil used by tobacco workers.

Dr. WILLIAM DYSON (Manchester) confined his attention to cases whose condition was, clinically and histologically, indistinguishable from the dermatitis known as eczema—in other words, a superficial non-microbic inflammation of the skin caused by external irritation in a predisposed subject. It was commonly seen in bleachers, dye-workers, chemical workers, plasterers, French polishers, and hair-dressers. The predisposing causes of this must be held to be hyperidrosis, xeroderma, ichthyosis, senile degenerative changes, debility, tuberculosis, anæmia. Once the condition had been set up in a person relapses

were frequent, and the question of relapse brought into the discussion that of sensitisation. Sensitisation to a specific irritant was very rare in trade dermatitis; but a general supersensitiveness of the skin after long-standing or repeated attacks of dermatitis was common. This was certainly contributed to by the absorption of toxins through inflamed and damaged epithelium. In over 50 cases he had had blood-sugar estimations done, and the results suggested that when sensitisation was present a high blood-sugar was to be expected. Also that when the products of inflamed epithelium were being absorbed, the blood-sugar content was higher than when these products were being discharged on the surface. On the hypothesis that this supersensitiveness might be an anaphylactic phenomenon, he had treated 17 patients with injections of their own blood so as to produce an anaphylactic state. Fifteen of these cases had suffered from relapsing dermatitis, for periods ranging from three months to 20 years. The result of this procedure was much the same as that from small doses of X rays—namely, the production of an antianaphylactic state. He considered that the prognosis in a first attack of this dermatitis was good in the absence of an obvious predisposing cause; it was bad if of long standing or if there had been repeated attacks. For prevention, or lessening the incidence, he advocated medical examination before a man was employed, and a periodic inspection of all the factory's employees.

Dr. N. HOWARD MUMMERY spoke of industrial dermatoses as seen in the clinic of a large food manufacturing and catering firm, which also carried out transport on a large scale. His aim as medical officer to that firm was to prevent recurrence of these dermatoses, and to make the period of absence from work as brief as possible. He sent to hospital only such cases as seemed to need in-patient treatment. The employers' liability in respect of these dermatoses did not seem to rest on any scientific or practical basis, but rather upon certified opinions of private or panel medical practitioners or factory surgeons, who in the main had an inadequate knowledge of these diseases. His own view was that most dermatoses met with in industry were not due to the employment, neither were they more prevalent in industrial than in other walks of life. Rather were they due to constitutional susceptibilities of all degrees. Exclusion from a particular employment of those unfitted for it was a first necessary step. He rejected from duties requiring the handling of food all who had a skin disease, and those showing marks of seborrhœic and other states. The commonest predisposer to dermatitis was an unusually dry and inelastic skin. For many years he had carried out at the firm in question a weekly inspection of the workers. The initial lesion was a dry patch of interdigital or extensor coccogenic eczema. He recently had two cases arising from the cheese used in the production of Welsh rarebit. A person might work in a factory for years without skin trouble, and then suddenly develop a dermatitis, without having had any change of occupation. When that subsided he might remain clear for another series of years. Usually he had concluded that the fault lay with the worker rather than with his work. He did not think bakers' itch could be regarded as a clinical entity, and cases of it were rare in a modern bakery. In the staff of 5000 there had been 170 cases of skin disease in one year, and the lost time on that account averaged 18 days per case.

Dr. HENRY MACCORMAC submitted that there were two groups of cases. In one, the eruption was due to a known external agent, the reaction from that agent being of a specific type; instances were chromium ulceration and tar-workers' cancer. In the second group were cases much more difficult to understand. They were the non-specific types of eruption, generally eczematous, which occurred in people working at various occupations. Examples of this were bakers' and grocers' dermatitis. In many of the cases in this class it seemed likely that the patients were people who developed eczema while working at a certain trade; whether the work caused the eczema was not clear. He tried to arrive at some conclusions about this second group by inquiring among photographers who used metol or amidol. In one firm there were four men. One of them worked for ten years and kept free from dermatitis; another worked there six years before developing it, and since then had kept himself free by wearing gloves; another worked five years with freedom; another worked three years, had an attack after the first year, and was able to protect himself with gloves. The head of one firm said he had himself worked with metol for 20 years and had been quite free from any eruption; but on two occasions while on holiday he had developed eczema. If this eczema had occurred during his work it would probably have been attributed to the chemical. In one large school of photography 250 students had been constantly working at photography with metol and amidol, but there were only four cases of dermatitis, probably due to amidol. He carried out cutaneous tests in two of the cases, and neither of them gave evidence of specific sensitisation to metol.

Sir THOMAS LEGGE said there were people, incapacitated by trade dermatitis, who were receiving no compensation for it, simply because they did not know how to get it. Some were receiving the best form of treatment, but had been told nothing about the compensation to which they were entitled. Application to the certifying factory surgeon for the district, with the payment of 5*s*., was the only formality required. He urged that it was the duty of the doctor seeing such cases to tell the patients what they were were entitled to. Dr. Howard Mummery had shown how much good could be done by whole-time medical officers of factories; but how many factories had a whole-time doctor?—probably not 50 in the whole country.

Dr. W. J. O'DONOVAN said he feared that if this matter had been solely in the hands of the professional dermatologist the great mass of occupational dermatitis would have remained undiscovered. Now, however, the pendulum seemed to be swinging in the wrong direction, resulting in the figures being inflated. A prominent cause of this was the incursion of administrators, lawyers, and accountants. If a workman presented a certificate stating that he could not work because of dermatitis, he was at once asked (with a strong suggestion that dermatitis was usually occupational) to go to the certifying surgeon. In this way cases were almost forced into the occupational group. He had in his ward cases of chilblains and lupus erythematosus which had been certified as of occupational cause.

Dr. R. PROSSER WHITE agreed about the importance of the horn cells of the epidermis as a barrier against dermatitis and infection. He was convinced, however, that it was necessary to know the exact physico-chemical action on the skin of the particular drug used. The reason alkalis loomed so large in the causation of these dermatoses was that alkalis were solvents of the horn cells. The question of sensitisation was a very difficult one, but he thought the present tendency was not to assign a very great importance to it.

Dr. ALLAN PARSONS referred to an investigation of bakers' itch which he had carried out a few years ago for the Ministry of Health. Dr. Overton's remarks had convinced him that this subject was being carefully watched. He had also inquired into the dermatitis which occurred among hop-pickers. These people suffered from cracks and abrasions of the skin due to pulling the hops off the vines. A band of workers was giving attention to the subject.

Dr. G. H. LANCASHIRE gave an analysis of 100 cases, diagnosed as occupational dermatitis, which he had examined; 13 per cent. were not due to trade conditions, though they were certified to be so by the factory inspector; 20 per cent. of the cases were due to exposure to aniline dyes; 7 per cent. to bakers' itch; 18 per cent. were in rubber workers; 12 per cent. were among painters, largely due to turpentine or its substitutes, used for hand cleansing after work. Other trades represented in the list were cement

workers, hairdressers, grocers, electro-platers, brass-tube moulders.

Dr. F. E. FREMANTLE (President of the Section of Epidemiology), proposing a cordial vote of thanks to the speakers, referred to the value of the Society as a body of experts to whom the Government could refer on subjects such as that now discussed. He hoped this would be done in the future in increasing degree.

MEDICO-LEGAL SOCIETY.

AT a meeting of this Society on March 21st, the chair was taken by Sir WILLIAM WILLCOX, the President, and a paper on the

INVESTIGATION OF FIRE-ARM INJURIES

was read by Prof. SYDNEY SMITH. The investigator, he said, often wanted to know whether a given injury was due to fire-arms or not; the type of fire-arm responsible; the direction taken by the shot, and the distance of the muzzle from the body. Sometimes it was necessary to say whether one particular weapon had been used. The effects of fire-arms were very variable; a rifle bullet at the beginning of its trajectory, before it had settled into its regular spin, would wobble and cause a wound like a severe explosive injury; similarly a spent bullet, turning over and over, would cause injuries quite unlike those of a bullet wound. A small high-velocity bullet bored a clean hole; a slow large bullet often made a ragged one. Besides the projectile, the weapon produced a wave of gas, wads, unburnt powder, smoke, and flame, all of which (when the discharge was close enough) left their distinctive marks to aid diagnosis. Powder made tattoo-like marks on the skin, and left traces which could be chemically analysed. At a slightly longer range the wound made by a rifle bullet was a round, clean, punched-out hole surrounded by a zone of tissue denuded of its epithelium but showing little sign of blackening or burning; outside this there might be powder-tattooing. The hole itself might be surrounded by a black ring due to fouling from the bullet; this was sometimes mistaken for powder-marking. Local bruising due to hydrostatic pressure was also apt to be mistaken for the marks of a close discharge. These distinctions were important, as they might turn the scale between the theories of suicide or murder. Automatic pistols caused very much less blackening and burning than any other type of weapon, because of the completeness of the combustion of their "smokeless" powder. They produced a typical clean entrance wound. Exit wounds were nearly always torn, as the bullet was forced through the tissues. A low-velocity bullet caused the same kind of wound that might be made by a poke from a stick. In bone, such as that of the skull, the entrance was clean-cut and the exit had an excavated appearance. A line between entrance and exit, if produced, nearly always gave a good indication of the track of the bullet, but deviation sometimes occurred within the body if the projectile struck a bone. The appearance might give a guide to the direction; when the bullet entered at an angle the wound tended to be oval, and if the discharge had been at close range there might be much bruising and burning on the angle of fire. A shot-gun discharged within one yard caused a single wound, and within three yards slight scattering with burning and blackening, but above that distance the wounds of the separate shot were discrete and there was little discoloration. A sharp-pointed bullet might often inflict a wound very like that of a stabbing weapon, but the latter when pulled out tended to disturb the tissues, and their outward deviation distinguished the stab from the bullet wound. In bone the excavation effect of the dagger would be both inwards and outwards. Bullet wounds made at an angle might simulate cuts, but some portion of the tissue was generally removed, and there was often denudation of epithelium and bruising. Moreover, the bullet often left metallic traces. Bullets were sometimes marked by the cloth through which they passed. X rays were often valuable in demonstrating the absence of a bullet where the site of entrance escaped notice, or when great deviation had occurred within the body. When more than one injury was found it was important to pay careful attention to all the anatomical possibilities before deciding whether one projectile or more had been responsible. A bullet had been known to pass in a straight line through the back of a running man, through his abdomen, into the front of his leg, and remain embedded in the back of the leg.

Identification of Fire-arms.

Even if no projectile were found, a chemical and microscopical examination of the traces of metal and powder at the wound might give a clue to the kind of weapon which had been used. Some powders were filled with barium or bichromate. If an automatic pistol had been used, cartridge cases were often found at the scene of the crime, and the marks on the sides of these caused by the action of the weapon might be sufficient to identify one particular fire-arm. The distinguishing marks on a cartridge-case fired in an ordinary revolver were mostly on the base. A bullet which had passed through the bore of a weapon received not only the marks of the rifling, but also many minute scratches caused by individual faults. From the gross markings it was generally possible to tell the type of weapon which had been used, while from the smaller individual markings it was possible to prove whether or not a given weapon had fired the bullet. A bullet found in the body was weighed, had its specific gravity estimated, and its base examined for signs of the maker's name. The tip sometimes showed other signs which might identify it. The murderers of Sir Oliver Lee Stack in Cairo had been detected entirely by this means, and certain instruments with which they had notched the tips of their bullets had been found with metal still adhering that was identical with that of the bullets used. The apparatus used for the identification of bullets consisted of two microscopes fitted with a common eyepiece, so that the images of the two bullets to be compared were shown side by side. For macroscopic examination bullets were rolled on a sheet of plasticine; rifling was examined by taking a casting in sulphur and rolling the casting on plasticine. Bullets, however, were not always fired from weapons of the same calibre as themselves; a small bullet might be made to fit a large barrel by wrapping it in paper.

Some Extraordinary Projectiles.

Criminals had been known to pick up a bullet on a rifle range and fire it from a shot-gun. In one victim's body the investigators had found two shilling-pieces; the bullet had struck them when they were in his pocket and had driven them in without itself entering. A shot fired at a railway train had entered the dining-car and nearly killed an important personage. The projectile found had puzzled the officials, for it had appeared to be made of bronze, and to be roughly of 16-calibre. Many persons had been arrested, and all the guns in the district had been examined for traces of a bronze bullet. Closer examination, however, had shown that the projectile was flat on one side and rounded on the other, and that it had a splash of lead at its base. It had proved, in fact, to be a fragment punched cleanly out of a hinge of the table in the dining-car. The actual bullet had then passed through the door of the carriage. Traces of lead had been found, and also traces of some other substance which had at first been thought to be cupro-nickel and which had suggested a rifle bullet. This had thrown suspicion on the troops in the district, but analysis had proved the substance to be steel, a fact which had shown conclusively that the assailant had been the owner

of some continental ammunition which was known to possess a steel casing.

Sometimes metallic traces, too small in amount to be analysed, could be identified by means of the spectograph, but this method was still in its infancy.

A brief discussion followed, in which Mr. J. H. RYFFEL, Dr. MORGAN FINUCANE, Mr. BARRY O'BRIEN, Mr. W. M. WALKER, and the PRESIDENT took part; Prof. SMITH replied.

MEDICAL SOCIETY OF LONDON.

AT a meeting of this Society held on March 25th, the chair was taken by Dr. WALTER CARR, the President, and a discussion on the

MEDICAL INDICATIONS FOR THE INDUCTION OF ABORTION AND PREMATURE LABOUR

was opened by Mr. EARDLEY HOLLAND. Reviewing the legal and ethical position, he pointed out that the only lawful object of abortion was to save the mother's life or prevent serious injury to her health. The medical profession was trusted implicity and given the widest possible freedom of judgment. It had never been practicable to lay down strict rules for the medical indications, which had changed as medicine had advanced. The advent of insulin, for example, had made possible many pregnancies in diabetic women. Great difficulties occurred when social, personal, and economical factors added their weight to a medical indication which in itself might seem inadequate. The ethical standard had not been lowered by modern practitioners, but the modern gynæcologist was less fitted than his predecessors to form an opinion on the indications for abortion because he leaned more towards surgery and less towards medicine.

The medical indications might be classed as: (1) positive indications, (2) debatable indications, and (3) a heterogeneous and unclassifiable collection of combined medical, personal, and social considerations. Among the *positive* Mr. Holland put hyperemesis gravidarum of the toxæmic type; acute and chronic nephritis; chronic valvular disease of the heart with failure of compensation; pulmonary tuberculosis (about which there was great difference of opinion); Graves's disease; insanity, and certain cases of *Bacillus coli* pyelitis, which did not yield to treatment. The *debatable* indications included multiple arthritis deformans during pregnancy; hypothyroidism, such as early myxœdema; hyperthyroidism; albuminuria of pregnancy; eclampsia in a former pregnancy (a somewhat slender reason); certain cases of cardiac disease, and slight cases of pulmonary tuberculosis which might have a bad effect on pregnancy; former puerperal insanity; severe nervous or mental disturbances in early pregnancy due to fear in a former confinement, and as a better alternative to Cæsarean section than craniotomy. Very debatable were a new class of eugenical indications which might be termed "*fœtal.*" One of these was refractory syphilis, as for example in a case where, in a former pregnancy, the Wassermann reaction could not be brought to negative except by what was practically an overdose of arsenobenzene. Another was idiopathic epilepsy in the husband. It was interesting to contrast the hospital figures with those of private practice; the former showed a great preponderance of "positive" indications. From 1924 to 1927 inclusive, out of 4000 gynæcological operations, only thirty-one had been for the induction of abortion. Twenty-nine of the operations had been undertaken for "positive" reasons; eight of these had been for uncompensated cardiac disease, six for pulmonary tuberculosis, four each for nephritis and Graves's disease, and the remaining five for hyper- and hypothyroidism, tuberculous disease of the bladder, congenital syphilis. One had been for mental disorder in a previous pregnancy, and only one, on the grounds of "general bad health," came into the "doubtful" category. In the speaker's private practice of about 3500 patients he had induced abortion on twenty-eight occasions since 1919. The number of inductions performed for positive reasons had been only 19, a much lower proportion than in hospital. The grounds had been very varied. Of the six operations where the indications were debatable one had been on a woman of 45 suffering from debility, who had undergone a severe operation for an infected gall-bladder two years before and who had a family history of tuberculosis, and one on a patient just recovering from a long series of severe ailments which showed a very bad state of general health, and who had complained of exhaustion and rapid pulse; another had been for general ill-health, visceroptosis, a very recent bereavement and a consequent desire to join her husband in India immediately. These cases represented the class of patients about which the most difficult questions arose.

The induction of premature labour was quite a different problem. Apart from the toxæmias of pregnancy, the medical indications were not at all common. The principle in cases of later pregnancy complicated by disease was to treat the disease and neglect the pregnancy. This applied especially to pneumonia, in which the extra strain of an induced labour was very undesirable. Finally, so long as the physician were honestly intent on the welfare of his patient and believed that she would benefit by the operation, he could not possibly exclude extra medical considerations from turning the scale in doubtful cases where a medical indication existed.

The Cardiological Aspect.

Dr. B. T. PARSONS-SMITH emphasised the very serious consequences which pregnancy imposed upon patients suffering from structural heart disease. Even under the most favourable conditions an additional strain was inevitable. The blood volume was increased; diaphragmatic excursion was especially restricted, limiting the functions of the thoracic viscera, and metabolic changes took place as a result of impaired endocrine balance. It might be concluded that, by causing these additional stresses, pregnancy would further deplenish the circulatory reserve and favour decompensation. Management of the patient was a very serious problem; the physician must satisfy himself as far as possible whether the cardiac reserve was likely to be equal to the additional strain, or whether compensation might be failing or already exhausted. Either of these events might necessitate the termination of pregnancy. Circulatory failure was, however, an extremely variable quantity. In its minor forms it need not obviate the successful conduct of pregnancy, but when well developed it might be an indication to terminate. Statistics covering 15 years' experience at Queen Charlotte's Hospital showed that, out of 196 cardiac cases, 49, or 25 per cent., had had their pregnancies artificially terminated. Abortion had been induced in five cases (2·5 per cent.); premature labour had been induced in 34 cases (17·5 per cent.); Cæsarean section had been performed at term in 10 cases (5 per cent.). Of the remaining 147 patients, 119, or 60 per cent., had gone on to normal labour at term, although all of these had had gross structural disease with some failure of compensation. Thirteen had had a spontaneous premature labour after the twenty-eighth week; three had aborted spontaneously, and 12 had died undelivered. Excluding these, the death-roll was two (40 per cent.) after induction of abortion, seven (20 per cent.) after induction of premature labour, one after Cæsarean section at term, three after spontaneous premature labour, and seven after spontaneous delivery at term. The high mortality-rate after artificial abortion was significant.

One of the most important clinical factors for assessment was the myocardial degeneration and the

degree of its compensation. From the point of view of congestive heart failure the indications were persistent tachycardia (120 or over); cardiac dilatation; diminished tone of the first heart sound and gallop rhythm. All these were very serious. Then there was the pulse of 120 or over at rest, and the irregular action typical of auricular fibrillation; venous stasis; venous engorgement; œdema; pulmonary, renal, and gastro-intestinal engorgement; a respiration of 20 or over; orthopnœa; attacks of cardiac asthma, and pulmonary œdema. Whether these were primary or the outcome of valvular disease or myocarditis, their development during pregnancy might be a sufficient indication for its termination unless they responded promptly to treatment. Even if compensation were restored, induction might ultimately be necessary, and in the presence of gross cardiac failure it entailed grave risks. Other possible indications were various forms of valvular lesion, hastening decompensation; mitral stenosis, and aortic incompetence. There was little to choose between the gravity of these two conditions; myocardial reserve was the deciding factor, but when they were combined the risk was far greater. Hence the importance in all doubtful cases of an electrocardiogram to determine the presence of defective muscle function and to differentiate between the various forms of arrhythmia which might coexist. Auricular fibrillation was of outstanding importance in most women of child-bearing age; it represented the mitral late stage of chronic rheumatic carditis, and was a disastrous complication which necessitated induction. According to Dr. G. H. Hunt, 40 per cent. of these cases died during pregnancy, and 50 per cent. suffered from decompensation. In his group of mitral stenosis cases without enlargement there were no deaths, and only 3 per cent. developed failure during pregnancy. In the group with enlargement there were 12 per cent. of deaths and 27 per cent. developed decompensation phenomena. Signs of arrhythmia and premature contractions might generally be disregarded entirely; paroxysmal tachycardia and auricular flutter were important only in so far as they failed to respond to adequate treatment. Heart-block might be associated with serious defects in the myocardium but, if uncomplicated, its effects on the circulatory function in pregnancy were likely to be minimal. Three cases of partial and one of complete heart-block had progressed successfully to normal labour. The physician should assume that the majority of cardiac patients would develop some degree of failure during pregnancy and that suitable antenatal care would enable most of them to maintain adequate compensation. In a few cases, however, heart failure might be so grave and refractory as to threaten health and life.

Dr. BERNARD HART then read the paper which appears on p. 658 of our present issue.

Pulmonary Tuberculosis.

Dr. GEOFFREY MARSHALL described his experience with a group of pregnant women suffering from active pulmonary tuberculosis. It had been very difficult to decide in any given case whether the indication was positive or doubtful. In the first place, it was impossible to group the cases according to the amount or extent of lung tissue involved. Roughly, where the patient had been known to suffer from definite symptoms of pulmonary tuberculosis for a great many years, in spite of the fact that the lesion might be fairly extensive, she might be expected to complete her pregnancy and labour without coming to great harm. Where, however, the disease was recent, one might expect the most tragic degeneration of condition; patients with short histories should therefore have pregnancy terminated. Patients with pulmonary tuberculosis reacted badly to any kind of surgical intervention, having prolonged pyrexia and in most cases showing signs of extension of the disease. On the whole they suffered less harm if they were allowed to go on to the fourth month and then had the uterus emptied by abdominal section.

Discussion.

Dr. ANTHONY FEILING remarked that patients with Graves's disease did not often conceive, but of those who did, Dr. Gardiner-Hill had found that very many stood their pregnancy extremely well. The indication for abortion in nephritis depended on the severity of the condition; not every case of acute and chronic nephritis need have abortion induced. Patients with true myxœdema practically never conceived, and there was no need to terminate pregnancy for the milder degrees of thyroid insufficiency. There must be very few cases indeed where it would be justifiable to cause abortion on account of epilepsy in the parents; only 30 per cent. of epileptics had an epileptic heredity. He asked how Dr. Hart distinguished between women who threatened suicide without intending to carry it out, and those who were really likely to fulfil their threat.

Dr. H. B. DODWELL mentioned three young married women who never passed a winter without severe paroxysmal asthma, producing considerable strain on the heart and a condition quite grave enough without the additional strain of pregnancy. He also knew one epileptic woman whose attacks would almost certainly constitute grave risk to her child if she bore one. She had had one baby whose life had been endangered many times in the first two months.

Mr. T. C. CLARE advocated sterilisation of women whose pregnancies were interrupted for medical reasons. A pregnant unmarried woman who had consulted him had not asked him to terminate pregnancy, but had been worried because she had only one kidney. She had also had a slight degree of pyelitis. Was abortion justified?

The CHAIRMAN mentioned severe chorea as a possible indication for abortion. He did not agree that induction was necessary for myxœdema; the myxœdema of women who became pregnant was said either to be very slight or to be curable with thyroid. The amount of thyroid required to keep the patient in fair condition was immaterial. Phthisis was said to flare up acutely after natural delivery; did it do so after induction?

Replies.

Mr. EARDLEY HOLLAND agreed that there was no strict necessity to induce abortion for myxœdema, but nowadays it was usual to give the patient the benefit of the doubt. Epilepsy in the father did not constitute an indication from the purely medical point of view. He had had to do Cæsarean section under spinal anæsthesia because of acute dyspnœa at the end of pregnancy in a case of Graves's disease and in one of simple goitre. It was wonderful how cardiac cases bore pregnancy if kept in bed; he allowed them to go to term and on the tenth day sterilised them by excising a loop of the Fallopian tube under local anæsthesia. The operation was trivial and took about 12 minutes. It was said that the placenta swarmed with tubercle bacilli, both after labour and induction, and thus constituted a focus of infection, and that therefore labour should be terminated by hysterectomy. Pyelitis in a single kidney was certainly an indication for abortion.

Dr. PARSONS-SMITH said that the artificial termination of pregnancy was less often justified in primiparæ than in multiparæ.

Dr. BERNARD HART agreed that it was extremely difficult to decide which threats of suicide were to be taken seriously; he had no hesitation in giving the benefit of the doubt. It depended partly on the history and partly on the precise clinical picture, particularly such things as interference with sleep and impairment of the bodily condition, which made the risk very serious.

EXTENSION OF BURTON-ON-TRENT INFIRMARY.—Property adjoining this hospital has been purchased for the erection of extensions. The new buildings will include new X ray, artificial sunlight, and ear, nose and throat departments, a lecture room, and a recreation room for nurses.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF OBSTETRICS.

AT a meeting of this Section held on Jan. 25th Sir WILLIAM SMYLY took the chair in the absence of the President, and there was a discussion on

Radium Treatment of Uterine Carcinoma.

Dr. BETHEL SOLOMONS showed a uterus which he had removed by the Wertheim method.

The woman was a multipara of 57. Her regular menstruation ceased for four years, but a year ago she started to bleed irregularly. On examination a typical squamous cancer of the cervix was found; it bled easily on examination, and seemed to be fixed to all the fornices. It was a borderline but somewhat dangerous operative risk. Radium was inserted and the patient was closely watched for four months. Gradually the appearance became nearly normal, but as she had two hæmorrhages during that time, Dr. Solomons decided to remove the uterus.

A microscopic report from Dr. F. P. J. Burke stated that "the glands show no abnormality, there is no evidence of malignancy, and the muscle walls show a good deal of hyaline change." There was no excessive fibrous tissue during the operation, but the left ureter was slightly out of its usual position. Recovery was uneventful.

Dr. W. C. STEVENSON, who had given the radium treatment, said that the dose in this case was rather larger than usual, because he had given it in more than one place. He had begun treatment on Oct. 2nd and continued it for 72 hours. On the fourth day the patient had taken some meat extract, after which she developed severe diarrhœa. Dr. Stevenson has used 49 millicuries of radium, and the one place he had been afraid of was the rectum, so he had kept the radium as far away from it as possible. The cavity of the uterus was 7 cm. long, and the radium tube was left for 24 hours, and was then pulled down a further 2 cm. and left for another 24 hours; at this time it was just at the cervix.

Dr. W. A. TAYLOR said that the sequence of events described in text-books had not occurred in this case. The stage of hyperæmia had developed when the patient had suffered from diarrhœa, but there had apparently been no stage of sloughing, as nothing in the nature of a slough had come away. After the diarrhœa ceased the condition of the cervix very rapidly improved; in fact, it appeared to be healed. At the present time cases of carcinoma of the cervix were divided in the literature into operable, borderline, and non-operable, cases. He personally thought that radium removed the borderline cases, as all surgeons now decided to see what radium would do for these cases before operating. The question of giving this patient a further course of radium had been considered, but she had passed from a condition of parametric involvement to one in which no parametric involvement could be found, and so it appeared that the time for operation had come.

Dr. D. G. MADILL said that in this case he would have removed the uterus. He asked how many needles had been used, and where they had been inserted.

Dr. A. H. DAVIDSON asked if Dr. Solomons had experienced any difficulty in carrying out the operation, as it was generally supposed that after radium treatment a lot of fibrous tissue formed which made the carrying out of a Wertheim operation difficult. He thought it possible that the hæmorrhages were fibrotic, and wondered whether the radium treatment would not have been sufficient, and whether the operation was necessary or beneficial. Radium got mostly at the nearer cancer cells and not at the further ones, but if in this case it had reached the further cells and killed them, then operation would not have been necessary.

Dr. R. STUMPF said that there were three ways of treating cases like the one described by Dr. Solomons —radium, deep X ray therapy, or combined treatment by X rays and radium. According to recent statistics, the results of each of these treatments were about the same, and it had been stated that the results of radiotherapy in operable cases were practically the same as those of operation. In borderline cases cure by radiotherapy could be obtained in from about 10 to 15 per cent. Considering that operative technique in these cases could hardly be improved, and that radiotherapy was only in the early stages, he thought it likely that the time might come when operation even in operable cases would be abolished, and all cases would be treated by radium.

After further discussion Dr. STEVENSON said it was sometimes difficult to know how long to wait after radium treatment before operating. In the present case the treatment had been very severe, and the operation had been performed nine and a half weeks afterwards, and he thought that this was about the right time to wait. He had not used needles at all, but had used the screen method by which it was possible to give a much more diffuse dose, and one which was more likely to effect the parametrium.

Dr. J. S. QUIN read a paper on

Scopolamine-morphine Narcosis in Labour.

He considered it important that the first injection should be given to the patient as soon as labour had started and a further injection after the child was born. In 25 per cent. of the patients treated he had found that the result was "very good," in 15 per cent. the result was good, and in 10 per cent. there was no apparent benefit from the treatment.

Dr. MADILL said it had been stated that after the judicious use of scopolamine-morphine the patient would pass into a somnolent state and would go into labour, and that labour would pass over without the patient remembering much, if anything, about it. His experience was that scopolamine-morphine had not been as successful as this. He noticed that Dr. Quin, out of 61 cases, only regarded 15 as complete successes. Failure was sometimes attributable to want of complete silence in the patient's surroundings. In his opinion scopolamine-morphine was not the ideal anæsthetic in obstetrics. He thought that rectal ether had great possibilities.

Dr. SOLOMONS said he did not advocate twilight sleep as a general measure, but thought it should certainly be given to the primigravida who dreaded childbirth, and the multipara who had had a bad time on her first confinement, and who looked forward with fear to the second. There was no doubt that the method was not ideal, and that babies were often born "blue." The room should never be darkened, for it was necessary that the nurse should have a good view of the patient. He thought a great deal of harm had been done by advocacy of the method in the lay press, and by the establishment of "twilight sleep homes" in charge of doctors who were not always specialists in obstetrics.

Dr. F. W. DOYLE referred to a gas-oxygen apparatus which had recently been installed at the Coombe Hospital, and said that this method was now being used in America, apparently with excellent results. Gas-oxygen could be given with perfect safety to both mother and child, and did not interfere at all with the progress of labour; ; in fact, it was claimed that it accelerated rather than retarded its progress; nor did it interfere with lactation.

Dr. A. H. DAVIDSON thought that the great disadvantage of scopolamine-morphine narcosis was the supervision required. It would not be easy for a busy obstetrician to visit a patient every three hours, but if the nurse could be sufficiently trained to give the injection and to see that the patient did not come to any harm from it, it would be a different matter.

The CHAIRMAN, referring to the rules laid down for the beginning of scopolamine-morphine injections, said that he thought when labour became painful

was the right time to begin the injection, without any physical examination. The treatment seemed to him to be one which would be confined to the first stage of labour. Most patients in private practice insisted on getting some kind of injection. Scopolamine-morphine was certainly not ideal, but he had found that it eased patients and helped them greatly in the first stage. Its great drawback was the uncertainty of the result. Many cases in which it appeared to be absolutely useless turned out to be the best.

Dr. D. J. CANNON showed a specimen of Chronic Metritis, and a discussion followed.

Reviews and Notices of Books.

ŒSOPHAGEAL OBSTRUCTION.

Its Pathology, Diagnosis, and Treatment. By A. LAWRENCE ABEL, M.S., F.R.C.S., Assistant Surgeon, Cancer Hospital; Surgeon, London Lock Hospitals. London: Humphrey Milford, Oxford Medical Publications. 1929. With 132 illustrations and 2 coloured plates. Pp. 245. 30*s*.

THE surgery of the œsophagus teems with many problems which are not capable of solution by ordinary surgical methods. The practitioner in this department of surgery must have special training in methods of investigation as well as be alive to the factors which render the application of surgical principles suitable to other parts of the body of little use in this region. The author of this book seems to be well equipped in both these respects. He gives a good account of all forms of œsophageal obstruction, prefacing the main substance of his thesis by two chapters on anatomy and what has of recent years been referred to as pathological physiology. It is interesting to note that Mr. Abel finds he can perform the very unpleasant examination with the œsophagoscope in the vast majority of cases without any anæsthetic, local or general. Whether he can do this without a preliminary education to tolerance by the passage of bougies is not stated. Less expert clinicians usually find that at least local anæsthesia is necessary in a previously untreated patient.

An important section is that on cancer of the œsophagus. Unlike some workers in this field, Mr. Abel believes that the disease gives signs of its existence early and that it remains localised long after its presence can be diagnosed. He states that glandular metastases are the exception rather than the rule, and believes that surgical removal will ultimately become a feasible operation with a risk not too great. Just how the extreme difficulties of access, suture, avoidance of infection, and shock are likely to be overcome he gives no hint; but the possibility that some progressive step in the raising of immunity before operation may change the whole aspect of the problem must not be lost sight of. Indeed, if treatment by some other method has not displaced the excision of malignant disease this may confidently be anticipated. A fair summary of work which has been done with radium is given by Mr. Abel, who seems to think that there is a certain field also for diathermy treatment.

All surgeons interested in disease of the œsophagus should read this book. There are good and useful bibliographies appended to each chapter. Numerous explanatory illustrations, including radiograms and some coloured œsophagoscopic appearances, add greatly to its value.

SURGICAL DIAGNOSIS.

Handbook of Surgical Diagnosis, By CLEMENT E. SHATTOCK, M.D., M.S. Lond., F.R.C.S., Surgeon to the Royal Free Hospital; Assistant Surgeon to the Cancer Hospital. Edinburgh: E. and S. Livingstone. 1929. Pp. 678. 15*s*.

THIS handbook systematically describes the appearances, symptoms, and differential diagnostic points of the various surgical conditions. The book is arranged on a regional plan, so that all forms of peritonitis, for instance, are considered together however different their symptoms. Internal hernia, which comes to the surgeon usually under the guise of acute obstruction, is grouped, because of its name presumably, with ordinary inguinal or femoral herniæ which present themselves as tumours in the groin. It would possibly have been better if the author could have grouped his subject matter according to the most prominent symptom, but, since Mr. Shattock has had considerable teaching experience, the arrangement is doubtless founded on the plan which he has found to be the most helpful line of approach to clinical diagnosis. There are numerous skiagrams but no other illustrations. The information set out in the handbook is reliable and the student will doubtless derive considerable help from its pages.

Elements of Surgical Diagnosis. By Sir ALFRED PEARCE GOULD, K.C.V.O., C.B.E., M.S., F.R.C.S., late Surgeon to the Middlesex Hospital. Seventh edition, revised by ERIC PEARCE GOULD, D.M., M.Ch. Oxf., F.R.C.S. Eng., Surgeon to Out-patients at the Middlesex Hospital. London: Cassell and Co., Ltd. 1928. Pp. 730. 12*s*. 6*d*.

THIS small volume on surgical diagnosis needs no introduction since it has been a popular student's manual for many years. It was first published in 1884 and the original form is still retained, a striking feature being the separation of the diagnosis of injuries from the diagnosis of diseases. It is six years since the last edition was published, and Mr. Eric Pearce Gould, who has revised several editions, has made some alterations and additions in the present volume. An introduction dealing with the methods of surgical diagnosis has been substituted for the first three chapters of previous editions; cholecystography and the use of lipiodol are mentioned for the first time; and many new X ray plates have been added. The seventh edition fully maintains the high standard of its predecessors.

NELSON LOOSE-LEAF LIVING SURGERY.

Edited by ALLEN O. WHIPPLE, M.D., and FORDYCE ST. JOHN, M.D. Vol. VII.: Gynæcology and Surgical Obstetrics. Supervising Editor: ARTHUR H. CURTIS, M.D. New York: Thomas Nelson and Sons; London: Waverley Book Co., Ltd. 1929. Pp. 729.

Vol. VII. completes this new system of surgery and is well up to the standard set by previous parts. The subject matter is divided up into 37 sections, written by 23 different authors. Neither normal nor abnormal labour is considered and the only obstetrical subjects other than those sequelæ of childbirth always included in gynæcological text-books are puerperal fever and Cæsarean section. A long informative and satisfactory chapter is devoted to the endocrine aspects of gynæcology; this includes accounts of the modern work on the ovarian hormone, and an interesting section on the pathology and physiology of the endometrium. When whole chapters can be assigned to conditions such as leucorrhœa and dyspareunia, which by the way is discussed with a frankness unusual in technical works, it seems unfortunate that space has not also been given to the consideration of dysmenorrhœa which the practitioner is constantly called upon to treat. A particularly good chapter is that on puerperal fever; the principles of its pathology and the basis of treatment are well set out. The causes and treatment of lumbosacral and sacral backache are clearly described, also that interesting condition known as endometriosis.

Of those gynæcological affections for which radiotherapy has been employed, Dr. Curtis himself deals

with cancer of the uterus and myomata. He believes radium to have only a limited field of usefulness for destroying myomata and clearly states the indications and contra-indications. In his view, surgical removal must still play the major part in treatment. In exsanguinated individuals he has found preliminary feeding with liver, sweetbreads, brains, kidney, or ox-heart to be of great advantage, but in urgent cases he relies on blood transfusion to produce a rapid increase in hæmoglobin content. High fundic amputation is recommended whenever possible; this is good advice. When he is discussing the treatment of carcinoma of the cervix, the author does not seem to have made up his mind definitely as to the scope for operation and radium application. He refuses to be dogmatic and leaves the reader to choose for himself from data, which are really insufficient to afford guidance. He attributes to R. E. Fricke a statement that X rays alone have not cured a single case of cervical cancer in America.

Previous volumes of this system have been favourably reviewed in our columns. Now that the work has been completed the editor-in-chief must be congratulated on an excellent production. The numerous contributors have been selected with discrimination; the outlook of the book is modern and the subject matter well presented. It provides a uniformly reliable description of the principles and practice of the surgical art. That the editor intends the reputation of the book to be maintained is clear from some additions which have already come to hand. If future advances in surgery are added as promptly as the recent ones now sent us, and the supply is kept up, the practitioner who possesses this attractive work will be kept well up to date in current surgical literature.

LIPIODOL.

Diagnostic et thérapeutique par le lipiodol. By Prof. J.-A. SICARD, Médecin de l'Hôpital Necker; and Dr. J. FORESTIER. Paris: Masson et Cie. 1928. Pp. 370. Fr.50.

Lipiodol in the Diagnosis of Thoracic Disease. By F. G. CHANDLER, M.D., F.R.C.P., Physician with charge of Out-patients, Charing Cross Hospital; Physician, City of London Hospital for Diseases of the Heart and Lungs; and W. BURTON WOOD, M.D., M.R.C.P., Physician with charge of Out-patients, City of London Hospital for Diseases of the Heart and Lungs. London: Humphrey Milford, Oxford University Press. 1928. Pp. 134. 10*s.* 6*d.*

To the radiologist and to many surgeons and physicians interested in special branches of medical science, the work by the late Prof. Sicard and Dr. Forestier should prove a valuable work of reference. It contains the most authoritative and detailed account available of the uses of lipiodol at the present day. Inspired by the discoverer of this valuable diagnostic procedure, the chapters are marked by precision and restraint, and the numerous photographs and diagrams facilitate practical application. The well-known uses of lipiodol in pulmonary diseases, in the exploration of the pathological anatomy of the central nervous system, and in the examination of the urinary tract are fully dealt with, and less widely known applications of the method for exploring the accessory sinuses, the stomach, and the female genital tract open out avenues of future development. The fact that 66 entire pages are devoted to the bibliography illustrates the comprehensive nature of this excellent book.

Those who are specially concerned with the use of lipiodol in the diagnosis of pulmonary disease will find the 30 pages which comprise the text of the book by Dr. F. G. Chandler and Dr. W. Burton Wood attractive. They are followed by 47 well-printed radiograms which amply illustrate the commoner diseases in which the method is useful. It is a work of this compact nature which will be welcomed by the busy practitioner who has no leisure to master a lengthy survey of a subject not yet of daily importance in his routine.

ROCKEFELLER INSTITUTE STUDIES.

Studies from the Rockefeller Institute for Medical Research. Reprints. Vol. LXV. New York: Rockefeller Institute. 1928. Pp. 617. $2.00.

THESE reprints of papers, originally published in various journals by those working in the Rockefeller Institute or receiving grants from it, are of great value to any reference library. The most recent volume contains 45 papers covering an exceedingly wide field of research in pathology, biophysics, physiology, chemistry, clinical medicine, and experimental surgery. There are included papers on heart-block, crystalline structure, bullous impetigo, allergy, the permeability of thin, dry membranes, experimental sarcoma, Oroya fever, reciprocal effects of concomitant infections, and pneumococcal meningitis.

Dr. Fred. W. Stewart contributes two papers on pneumococcal meningitis with special reference to pathological anatomy and therapy. Dr. Simon Flexner shows that the ætiology of epidemic encephalitis has not been clarified by experiments with herpes virus in guinea-pigs. Posthumous articles by Hideyo Noguchi on the ætiology of Carrion's disease and the relationship between Oroya fever and benign verruga are included and an important composite article on nuclein-induced leucopenia and its dependence on the spleen. There are two papers on the antigenic complex of *Streptococcus hæmolyticus*, and two broadly philosophical articles deal respectively with ontogeny and hereditary diseases. The only purely clinical studies are on cardiac irregularities, heart-block, and chicken-pox. The plates, diagrams, and bibliographical tables in the original papers are reproduced in full.

A CATALOGUE OF SCIENTIFIC BOOKS.

Early Books on Medicine, Natural Sciences, and Alchemy. L'Art Ancien S.A. Zurich: 8, Pelikanstr. Pp. 722. Swiss Fr.12.

THE value of a catalogue of second-hand books to a collector is twofold: in the first place the vendor may be ignorant of the worth of some of the rarer books which turn up at times and are bought in parcels of miscellaneous printed matter, and the keen-eyed collector may acquire a bargain for an old song. This does not often happen. In the second place a well collated catalogue, such as this one, contains a great deal of history for the bibliophile, and forms a handy book of reference. This catalogue consists of 1988 items, with illustrations of title pages and an index and contains a very representative lot of the incunabula of the profession. We miss one or two items; for instance, it does not include a copy of Auenbrugger's classic on percussion, nor are Edward Jenner's inquiry nor any of John Hunter's works included, and Americans will search in vain for Beaumont's account of Alexis St. Martin. The prices are given in Swiss francs and vary from Buchan's *Domestic Medicine* (1784) at 8 Swiss francs to Bartholomæus Anglicus (1491–92) at 12,500 Swiss francs, and Albukasim (1471) at 15,000. There are no fewer than 18 Paracelsus items, mainly from the Georg Kloss Library, and oddly enough a few of the books bear the book plate of the House of Commons Library. On the whole, the prices seem rather high. English buyers may be interested in Jebb's edition (1733) of Roger Bacon's *Opus Majus* at 275 Swiss francs, and Grosseteste's *Commentaria in Posteriora Aristotelis* (1497) at 650 Swiss francs. Sixty Swiss francs for the New Sydenham Society reproduction of William Hunter's *Gravid Uterus* seems to us a heavy price. Finally we note that Sir Richard Manningham, a distinguished obstetrician, is entered as physician to the Royal Society.

TROPICAL DISEASES.

Manson's Tropical Diseases. A Manual of the Diseases of Warm Climates. Ninth edition. Edited by PHILIP H. MANSON-BAHR, D.S.O., M.A., M.D., F.R.C.P. London: Cassell and Co., Ltd. 1929. Pp. 921. 31*s.* 6*d.*

THE ninth edition of this manual of the diseases of warm climates follows the eighth within a period of four years, and in the interval the book has been reprinted once. The author remarks that in no other department of medicine have advances, both in diagnosis and in treatment, been so many or so striking as in the practice of medicine in the tropics, and the volume has been revised so as to take cognisance of the newest work on malaria, kala-azar, dysentery, and sprue. In spite of this successful attempt to keep the manual fully up to date, it remains a consistent whole and has not grown unduly in bulk; the result has been attained by judicious arrangement of type and by the free use of diagrams and illustrations, which in the present edition include 35 plates (23 of them in colour), 401 figures in the text, 6 maps, and 34 charts. The volume is indispensable for any who wish to acquire or retain an adequate knowledge of disease in all parts of the British Commonwealth. Tropical medicine is under no little debt to the author for the unremitting industry and vigilance which its compilation has entailed.

Die Malaria in ihrer Bedeutung für die Geschichte Roms und der Römischen Campagna. (Malaria in Relation to the History of Rome and the Roman Campagna.) A Historical Study. By the late ANGELO CELLI. Translated and edited by ANNA CELLI-FRAENTZEL. With an introduction by Prof. Dr. HENRY E. SIGERIST. Leipzig: Georg Thieme. 1929. Pp. 118. M.12.

THIS work is the outcome of Angelo Celli's investigations into malaria in the Roman Campagna, prepared for the first International Malaria Congress in Rome, and its posthumous publication has been made possible by the good offices of his various friends and admirers. It is an abridged edition of the original account which has been translated into German by his widow, Anna Celli-Fraentzel. Celli, as all the world knows, was one of the pioneers in the war against malaria, and his work in the Campagna produced the most brilliant practical results. Not only has malaria disappeared, but the antimalaria measures have resulted in the bonification of the agricultural land.

The subject matter of the volume consists of a review of the political and sanitary state of the Campagna in historical times, with an account of the methods inaugurated by Celli. The text is liberally annotated with references which occupy some 30 pages and will remain a monumental memory of one of the first and greatest practical Italian public health workers in this field.

Malaria Problems. By FREDERICK L. HOFFMAN, LL.D., Consulting Statistician, Prudential Insurance Company; Member, National Malaria Committee. 1928. Pp. 207.

ONLY those familiar with the subject can clearly realise the enormous economic consequences of malaria, in view of the fact that the mortality index is but a slight indication of the prevalence of the disease. On the basis of an assumed fatality rate of 1·5 per cent., there would be approximately 1,035,000 cases of malaria throughout the entire country during the course of a year. This small volume contains a number of reprinted papers on the malaria problem and represents many years of attention on the part of the author to a question of first-rate importance to large sections of the community. From 1916 onwards he has been organising an attempt to deal with the whole problem along more rational lines than have been followed in the past. From this has sprung the National Malaria Committee which has held sessions annually in conjunction with the meetings of the Southern Medical Association.

The greater number of the incorporated papers deal with the organisation of the Committee and the results which have already been achieved.

JOURNALS.

BRITISH JOURNAL OF CHILDREN'S DISEASES, Vol. XXVI., January–March.—Prof. F. S. Langmead contributes a paper on Some Disorders of Neuro-muscular Coördination in Children, in which he includes cardiospasm, Hirschsprung's disease, anal spasm without any local cause, congenital hypertrophy and dilatation of the bladder and ureters, and idiopathic hydronephrosis, and congenital pyloric spasm and pyloric hypertrophy.—In his paper on the Illness of Infection in Measles, Dr. G. F. Abercrombie reports personal cases of this rare condition, in which a child exposed to the infection of measles a few hours earlier shows physical signs such as slight rise of temperature, sneezing, conjunctival injection and even a morbilliform rash which disappear in a day or two but are followed by undoubted measles within the incubation period. Dr. Abercrombie maintains that the illness of infection in measles is much less rare than is usually supposed, but its signs and symptoms may be so transient and trivial as commonly to escape observation.—Dr. Hilda N. Stoessiger contributes a Note on Summer Diarrhœa, in which the methods of feeding in a number of recent cases of summer diarrhœa and vomiting in young breast-fed or bottle-fed infants are compared with those of a random single group of infants of similar age. No greater proportional incidence of infective diarrhœa could be demonstrated among infants fed on cow's milk than among those fed on dried or condensed milk. It is suggested that the maintenance of a cheap and clean fresh milk-supply will prove to be a safer way of preventing infective gastro-enteritis than the replacement of fresh milk indiscriminately by dried or condensed milk.—Dr. Leslie Cole records a Case of Tetanus Simulating Tetany. The patient was a male child, aged 2 years and 9 months, in whom the possibility of tetany was suggested by the nature of the spasms involving the limb muscles. The diagnosis of tetanus, however, was established by the short and fatal course, the complete absence of rickets or other spasmophilic manifestations, and the failure to respond to calcium chloride, hydrochloric acid, or parathyroid gland. Infection with tetanus had probably taken place through a perforated ear-drum.—Dr. A. Moncrieff and Dr. R. E. Steen describe a Case of Early Cirrhosis of the Liver. The patient was a boy, aged 9 years, in whom cholecystotomy was performed for jaundice which had lasted six weeks. Examination of a small piece of liver removed at the operation showed early fibrotic changes, microphotographs of which are reproduced. Recovery took place.—The abstracts from current literature are devoted to tuberculosis.

AMERICAN REVIEW OF TUBERCULOSIS, December, 1928.—I. D. Bronfin and Saling Simon, writing on cardiac lesions complicating pulmonary tuberculosis, contravert the opinion that cardiovascular disease with passive congestion of the lung is preventive of tuberculosis. There is a wide discrepancy between the figures given for the incidence of valvular disease in pulmonary tuberculosis ranging from 1·2 per cent. (Anders) to 15 per cent. (Burns). The authors found clinical evidence of valvular disease in 6 per cent. Artificial pneumothorax treatment should be administered very cautiously in these cases and discontinued as soon as there is any evidence of cardiac disturbance.—Benjamin Goldberg, Henry C. Sweany, and Robert W. Brown have studied the gross and microscopic changes found in the bowels of 230 patients who had died from advanced pulmonary tuberculosis, ulcerative enteritis being found in 80 per cent. In one case a continuous chain of ulcers was found

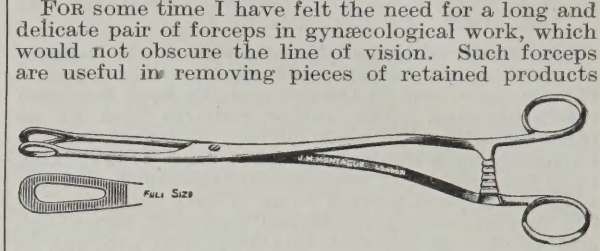
extending from the stomach to the rectum. Œsophageal fistula may result from the rupture of caseous hilar glands, and this was noted in two instances. Healing had resulted in a diverticulum in one case, in the other a permanent opening into a cavity in the broken-down gland was found. Intestinal perforations are relatively uncommon. A large number of lesions of the gastro-intestinal tract heal, as was evident in a few instances in which accidental death enabled an examination to be made. Ulcers of lymph follicles and submucosal tissue may heal without scar, those of deeper tissues lead to contractions and the formation of diverticula. Severe symptoms may result from slight lesions, while slight symptoms may be associated with grave ulceration. Incipient lesions are most frequently found in the lymphoid tissue about the ileocæcal valve.—W. B. Kendall and C. B. Ross survey the results of artificial pneumothorax after 14 years. The difficulty of securing proper "controls" for an investigation of this kind is obvious. Ideal controls to use in estimating results would be comparable patients who had refused similar treatment, but nowadays very few refuse to accept this form of therapy. Patients in whom collapse therapy has failed on account of adhesions, for example, have been used for comparison. Of the most recent group of cases (A.P. initiated 1923–1927) 66·9 per cent. of those who received compression are improved, well, or working, compared with 31·8 per cent. in the similar "uncompressed" group, the figures for patients able to work being 22·2 and 6·8 per cent. respectively. At the end of ten years 65·7 per cent. of those who had received treatment (complete or partial but fairly satisfactory collapse) were dead, while 92·5 per cent. of the control group were dead. The results achieved are still more striking if comparison be made between the patients in whom complete collapse was obtained and those in whom adhesions allowing a partial but preventing a complete collapse were present. The improvements which result from a partial collapse are usually only temporary. At the end of five years the difference between the total improvement shown by this type of compression and that of the controls has diminished to less than 10 per cent. A wider use of such surgical methods as phrenicotomy and thoracoplasty is therefore suggested.—A paper by McKahn and J. C. Torrey on the Development of Tubercle Bacilli is noticed on p. 696.

INDIAN JOURNAL OF MEDICAL RESEARCH. January, 1929.—The first paper in the present number is an elaborate epidemiological study of small-pox by A. J. H. Russell and E. R. Sundararajan. M. O. T. Iyengar contributes a comparative study of the larvæ of *Anopheles fuliginosus*, *pallidus*, and *philippinensis*. —R. Knowles and B. M. Das Gupta provide studies on the tricercomonas of the pig and a trichomonas of the porcupine.—Menon T. Bhaskara describes pathological changes in chronic appendicitis, A. N. Bose and B. N. Banerji the causes of ascites, P. A. Maplestone a simple method of preserving fæces containing hookworm eggs, and a redescription of *Wuchereria bancrofti*.—J. M. Henderson, N. K. De, and S. Ghosh contribute some hæmatological and serological investigations in leprosy.—V. T. Korke continues his observations on filariasis in some areas of British India, J. A. Sinton on Indian species of the genus phlebotomus, and together with W. Bird his studies in malaria with special reference to treatment.—J. Taylor and U. Thant have made observations on the vitamin B deficiency in pigeons; R. N. Chopra and his co-workers describe some medicinal plants from the Himalayas and the action of ephedrine and pseudoephedrine on the heart.—T. C. McCombie Young and Abdul Majid continue their observations on malaria in Coorg, and F. P. Mackie and N. Hamilton Fairley their studies on sprue, which comprise three important papers on the morbid anatomy, the blood changes, and the microscopical changes in the organs after death.

New Inventions.

A MODIFIED SPONGE-HOLDING FORCEPS.

FOR some time I have felt the need for a long and delicate pair of forceps in gynæcological work, which would not obscure the line of vision. Such forceps are useful in removing pieces of retained products

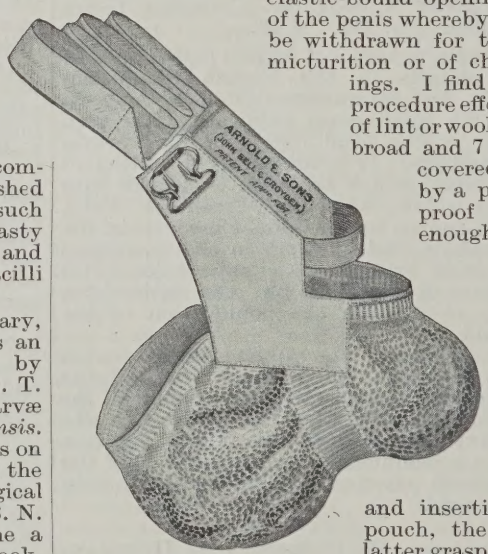


and polypi from the cervical canal, whereas similar forceps of larger size are apt to cause damage to the mucous membrane. I have therefore had made the forceps here illustrated. They can also be used with a piece of gauze for swabbing out the cavity of the uterus in suitable cases. Messrs. J. H. Montague, 69, New Bond-street, London, W., are the manufacturers.

REMINGTON HOBBS, M.D.

A NEW SUSPENSORY BANDAGE.

IN the treatment of gonorrhœa in the male I have found the suspensory bandage herewith illustrated appreciated by patients as a comfortable, convenient, and cleanly means of holding dressings in position. The bandage has a separate pouch for the penis in addition to the usual support for the testicles. This pouch is suspended from the pubic attachment of the bandage and is provided with an adequate elastic-bound opening at the root of the penis whereby the latter can be withdrawn for the purpose of micturition or of changing dressings. I find the following procedure effective. A piece of lint or wool about 5 inches broad and 7 inches long is covered externally by a piece of waterproof tissue large enough to overlap by nearly an inch all round and the double layer folded lengthwise over the penis. On turning the edges inwards over the dorsum and inserting within the pouch, the walls of the latter grasp the enveloped organ sufficiently firmly to give a comfortable feeling of support and to prevent displacement of the coverings. During withdrawal the penis is kept fully covered until clear of the pouch. The advantages of the bandage are: (1) Micturition and redressing can be performed by the patient without his having to undo any tapes and with no more exposure of the parts than would be required in normal circumstances. (2) Dressings are held securely in position day and night and can be changed without risk of soiling the fingers. (3) The support given to the penis adds to the patient's comfort in the acute stage and may help to prevent the development of epididymitis. (4) The isolation of the infective area within the bandage gives an effect of tidiness that assists the patient mentally. The bandage is manufactured by Messrs. Arnold and Sons (John Bell and Croyden), 50–52, Wigmore-street, London, W. 1.



A. GARDNER, M.B., Ch.B. Glasg.

THE LANCET.

LONDON: SATURDAY, MARCH 30, 1929.

A SANATORIUM COLONY.

THE National Association for the Prevention of Tuberculosis is about to make an interesting experiment at Burrow Hill. The well-known sanatorium owned by the society is being converted into one conducted on colony lines "for youths suffering from pulmonary tuberculosis in whom permanent arrest of the disease is ultimately likely to be secured." The age-limits are fixed at 14 and 19 years, and thus the whole of the adolescent period is included. Training in clerical work and gardening is to form an integral part of the scheme. The result of the experiment will be awaited with interest, but much of its value will be lost unless clear instruction is given to guide tuberculosis officers and others in the selection of cases. In the past lax diagnosis has too often obscured the results of sanatorium treatment. If a high proportion of the cases are non-tuberculous or doubtfully tuberculous—a state of affairs usually found in children's sanatoriums—the experiment will fail to answer the question whether a sanatorium colony for boys can enable the tuberculous adolescent to obtain permanent arrest of disease and fit him to compete in the open market when his training is over. Such is the ideal that the Association desires to attain.

Cases of pulmonary tuberculosis in adolescence may be classified in four groups: pre-adolescent phthisis; pulmonary tuberculosis of juvenile type ("primary infection" group); cases of pleurisy with effusion; and adolescent phthisis. (1) The pre-adolescent group will consist of the few survivors among children suffering from the adult type of infection who have reached the age of 14 years. There need be no doubt about the diagnosis, for besides the evidence supplied by physical signs and radiograms, tubercle bacilli can always be demonstrated in sputum or stools. The prognosis in such cases is hopeless and colonisation is obviously out of the question for these tragic cases. (2) The primary infection group consists of those boys whose history or physical signs suggest a latent infection, such a diagnosis being supported by radiographic evidence. Calcified nodes in the lung fields and calcified hilar glands are, however, evidences of healed tubercle and are usually seen in radiograms of the chests of healthy children. Before calcification has occurred radiograms afford no evidence of infection, physical signs are notoriously unreliable, and a diagnosis which depends upon guess-work does not justify sanatorium treatment. When a radiogram shows widespread nodes or definitely enlarged calcified glands sanatorium treatment may be indicated, especially if the patient is poorly nourished or subject to cough. But in general calcifications suggest acquired immunity rather than any special susceptibility to further attack from either endogenous or exogenous sources. (3) Pleurisy with effusion may be either demonstrably tuberculous, tubercle bacilli being found in the fluid, or a tuberculous origin may be diagnosed with reasonable certainty by a process of exclusion. (4) It would be well if the term "consumption" were limited to cases of adolescent and young adult phthisis. The gravity of the prognosis of this condition would then be recognised more clearly. The finding of the tubercle bacillus in the sputum of an adolescent who belongs to the industrial class is almost a sentence of death. Even if tuberculosis is discovered at a stage when the disease is localised, and the best modern methods of treatment are wisely applied, death within a very few years is probable. It is necessary to insist upon this melancholy fact Those who subscribe to schemes for the educational training of the young consumptive should realise that the large majority of the pupils may not survive to follow a career. This may be said without prejudice to the beneficial effects of occupational therapy. Idleness is most detrimental to the mental and physical interests of sufferers from a chronic disease. Further, a few of the stricken will survive and of these few most will be fit to follow some quiet occupation.

The Burrow Hill Sanatorium Colony is to provide beds for 60 "arrested cases" and 20 for patients "in the earlier stages of the disease." As the colony is intended to meet the needs of the whole country there should be no difficulty in finding suitable candidates. The patient with arrested disease is presumably one who has already spent one or two years in a sanatorium. Unfortunately experience has shown that the adolescent male consumptive as a rule prefers a death whose imminence he cannot realise to confinement in an institution. For those who have already "made good" in a sanatorium and possess the necessary determination the colony should provide an admirable school. It is unfortunate, however, that reference is made in the prospectus to "the earlier stages of the disease." The old teaching that tubercle commences as a limited focus at the lung apex and progresses by extension from apex to base can no longer be maintained. We now know that the onset of pulmonary tuberculosis in the young adult is usually an acute process, associated with an infiltration situated below the clavicle and that within a few weeks of the onset of the first symptoms of the disease there may be widespread involvement of the lung. The "early case" of the "T.B. minus" group—that refuge of the diffident tuberculosis officer—does not require sanatorium treatment. One who is usually already the subject of a depressed mentality and debilitated constitution should not be sent to live in the company of those who are suffering from a malady always dangerous and often fatal.

THE UNITY OF THE PERSON.

IN the latter part of the nineteenth century the advances in sciences ancillary to medicine placed pathology upon a sound observational basis, and it seemed reasonable to expect that bodily processes in health and disease could be fully expressed in terms of chemistry and physics. Bacteriological discoveries came into line with this expectation, for the reactions between parasite and host were found to depend upon the production of substances whose behaviour, even if their composition resisted analysis, could be summed up in chemico-physical language. Certainly there was in the background a vague theory of vitalism, which postulated a principle distinct from those governing the behaviour of non-living substances, but every advance in laboratory science seemed to diminish the territory in which such a theory could find a foothold. Medical science was confined to what could be seen or handled, weighed, or measured, and even if conceptions had sometimes to take the place of observation they were assumed to deal with the same order of things. The

modern use of the word "neurosis," for example, to denote alterations in behaviour or emotion, followed upon speculations concerning the relations of psychic and neural activity, and calls up a picture of something pathological that could be seen if only our instruments of observation were perfect: but, although an intimate connexion must exist between psychic and neural activity, yet to describe a known activity in terms of the unknown seems to be a straining of hypothesis in order to maintain a particular philosophy. This philosophy, unchallenged for half a century, profoundly affected our outlook, and the study of the patient as a whole, of his mental or emotional states, received till recently but little recognition in medicine.

The first intrusion into our settled beliefs, much resented by some, came from the psycho-analytical quarter and, whatever may be the ultimate fate of psycho-analytical theory, the influence of unconscious processes in the production of what we call functional nervous disorders is now widely accepted. Clinical psychology, however, seemed to have little to offer in the understanding of undoubted organic disturbances, although a close study of the literature shows a surprising variety of conditions in which shock or worry are said to be exciting causes. What appear at first sight to be typical physico-chemical phenomena have given Prof. KARL HANSEN, of Heidelberg, the opportunity to enlarge upon what he calls "the unity of the person" in a paper on allergic and psychic factors in asthma, read before the Section of Medicine of the Royal Society of Medicine and reported in our issue of March 2nd. He took as his text the case of a woman who showed sensitivity to horse-dandruff and bed-feathers, but whose asthma always set in when a situation was created that awakened a severe inner conflict from which she could find no escape. When the crisis was over the attacks stopped, whether the patient had found a real solution or apparent relief through transference. This single example may be compared with observations made at Edinburgh (THE LANCET, March 9th, p. 517), which showed that psychic disturbance caused attacks in 40·6 per cent. of cases of asthma there investigated, and a recent correspondence in our columns showed that there was need for some hypothesis that would correlate observations made by those who approached the subject respectively from the physical and the psychical side. Prof. HANSEN takes the general view that psychical factors influence the disposition to disease in the presence of known pathogenic substances influencing the organs, and to illustrate this view turned to allergic diseases in particular, the dependence of which upon psychic influences was, he said, well known, the intrusion of the allergen only leading to asthma when the way was prepared by these influences. He suggested that even in the presence of an organic defect the symptom might have a meaning to the patient, in the same way that the neurotic symptom has a meaning which can be elucidated by analysis. Some important suggestions found expression in the discussion that followed the paper. Both PAVLOV'S experiments on conditioned reflexes and our recently acquired knowledge of the vegetative nervous system have been regarded as providing alternatives to the possibility of psychical factors influencing bodily processes. Accepting the principle of the unity of the person, the speakers found a place for these studies and looked to them to provide explanations of the mechanism by which this unity is maintained, or by which alterations in the psychic equilibrium find expression in bodily symptoms. Though this principle may appear new, yet it sums up conceptions that have been gradually developing, and it only needed to be enunciated for us to appreciate its usefulness in reconciling the views of workers who have approached the same problem by different routes.

BIOLOGICAL KNOWLEDGE.

WHATEVER else he may be as well, there is no doubt that man is an animal; he is in fact in most respects by far the best studied species of animal there is. In introductory addresses and on other occasions of exalted emotion, medicine is sometimes described as a branch of applied biology, and biology is sometimes called the handmaid of medicine; suspecting that they lay under some suspicion of being mere technologists, Sir ARCHIBALD GARROD, the late Prof. J. G. ADAMI, and others have been at some pains to indicate the points of biological importance which may arise from professional experience. Everyone agrees in short that biology and medicine are intimately related to one another, and the connexion has become still closer with the newer biology of this century in which function as well as form has its place. The trouble of maintaining and enlarging this relation is the trouble of relating any of the disciplines into which we classify knowledge to one another—the limited capacity of the human mind. The position in medicine and the medical sciences is dreadful enough; as our principal American contemporary said the other day, the plethoric condition of medical literature has assumed the purple tinge of a fatal polycythæmia. We doubt whether it is quite as bad as that; purges and venesection can help a great deal, and the *Quarterly Index*, *Physiological Abstracts*, and such publications may yet succeed in staving off the post-mortem at which the only conclusion could be that no one must write any more books or papers. Such a contraceptive verdict might do little harm to the progress of knowledge; it has been said that if we knew all that is at present known we should find that most of the problems we think need solution have already been solved. This is probably largely true, but writing papers is an excellent exercise for the writers and the ordering of their thoughts, and it gives a procreative outlet in these days of birth control. It would be a pity to stop it altogether, though it might have rather more eugenic restraint.

If this is the state of affairs within the field of medicine, how hopeless it may seem to bring medicine into any sort of effective contact with the whole scattered field of biology. But courage can achieve most things, and a first step has been made by the promoters of *Biological Abstracts*,[1] who in 1927 began a monthly publication with no smaller object than to summarise the whole of current publications in biology, to abstract the relevant parts of some 6000 journals and to make the results available to everybody. Judging from their first two years they have made a good start at what seemed at first an impossible task, and, aided by a grant from the Rockefeller Foundation, they have issued a periodical which no one can read, but which almost everyone can consult with profit. Biology as a whole is gathered up together, and so it is very much easier for outsiders to find out what is going on. Revelations come as often as not from browsing about a little outside one's own proper field. It would, we believe, be a mistake for Dr. J. R. SCHRAMM and his colleagues to try to include medicine in their purview; it has the largest

[1] University of Pennsylvania, Philadelphia, Pa., U.S.A. Personal subscribers $9 per year.

current literature of any subject and it is already tolerably well served by abstracts and indexes. Medicine, it is true, can make substantial contributions to general biological theory, but much of its literature is extremely specialised and often ephemeral, and we should be sorry to see the real value of *Biological Abstracts* endangered by overcrowding. It has yet to find its permanent feet in conventional biology, though it has done enough to show that it deserves all encouragement and support.

Quite recently, too, the literature of man has been enriched or encumbered—time will show which—by another quarterly edited by Prof. RAYMOND PEARL. "Human Biology" [2] is a record of research, not a review, and its object is to publish original contributions which have this in common, that they will tend to synthesize a general biology of man. The first number happens to contain one article of particularly medical interest in which an account is given of the methods in use at the Institute of Biological Research in Baltimore and the Johns Hopkins Hospital for the vast inquiry into the constitutional factor in disease which has gradually come into being during the last ten years. Others deal with the sex factor in infant mortality, the mental capacity of different races and so forth, and the editor professes once again his faith that there is no need to be solemn if you want to be serious; we should call his own note on the mortality of some brewery employees no better than frivolous.

Annotations.

"Ne quid nimis."

THE DRAMA OF NAPOLEON III.

AT the Royal Society of Medicine on Wednesday, March 20th, Dr. Leonard Williams told the story, with profuse illustrations on the screen, of the most dramatic figure of the nineteenth century, Charles Louis Napoleon Bonaparte, for four years President of the French Republic, which followed upon the fall of Louis Philippe, and from 1851, until the disastrous Franco-German War, Emperor of the French. The career of the Emperor as set forth by Dr. Williams amply proved the description given of him as an arch-conspirator, but the lecturer's main object was to show that the story possessed great medical interest. This also the disquisition proved, and we must assume that Dr. Williams was well documented before he definitely laid to the charge of pathological developments so great a share in the disastrous finish of the imperial adventurer's life. The early events of this life were told by Dr. Williams with deliberate brevity and a choice of caustic language that contrasted excellently with the grand, and often grandiose aspirations of Louis Napoleon; in a few sentences he covered the interval of intrigue and pleasure which is supposed to have suggested to Eugene Sue the character of Rodolphe; but he related the sensational story of the escape from Ham as such a story should be told, that is with gesture and with relish of the situations that were being depicted, and closed this part of his address with a description of the daring intriguer seated on the throne of France by what looked like popular acclaim, and married romantically to one of the most beautiful women in Europe. At this stage pathology enters and Dr. Williams described, in a way that was all the more terrible because simple words were used and flippant comments were interspersed, how the miseries arising from a vesical calculus helped to ruin the usurper's prestige in France, to alienate the affections of a profoundly ambitious spouse, to warp his judgment in the conduct of international affairs, finally to leave him the victim of unescapable tragedies. On the last passage in the life of Napoleon III., when as a sick and elderly man he sought refuge in England, Dr. Williams gave information that was probably new to his audience, and many, like ourselves, will wonder where support can be found for a daring surmise which would account for the closing scene of Louis Napoleon's life. The details of that scene are historical and were given in THE LANCET at the time.[1] The Emperor was submitted a few days before his death to two belated attempts to relieve him by lithotrity of a calculus whose presence could be easily associated with sufferings that he had endured for many years, and on the morning of the day when for the third time operative interference had been planned, he died before Sir Henry Thompson had commenced to operate. The account of the autopsy, signed by all the Emperor's advisers except Sir William Gull, was published in our columns, as was Sir William's minority report, and the documents were the subject of considerable comment from the medical point of view in many quarters, for they revealed circumstances which would usually be considered to constitute a bar against operative interference. It was not here that Dr. Williams did more than summarise contemporary documents; the sensational part of his address was to come when he suggested that the operations were undertaken at the Emperor's order. Louis Napoleon must have been told by Sir Henry Thompson, said Dr. Williams, out of Thompson's vast experience that the operative interference possible at that date would be extremely dangerous, but none the less the Emperor himself insisted. Why? asked Dr. Williams, replying, "Because Louis Napoleon was resolved to make an attempt to regain the French crown. He intended to make an Elba-like return in emulation of Napoleon I., and felt that such return could only be successfully staged if he rode with the troops."

THE BRITISH JOURNAL OF UROLOGY.

UNTIL this month no journal devoted to urology was published in this country, and the newcomer [2] fills an undoubted gap in English medical literature. Its editors, Mr. Frank Kidd and Mr. H. P. Winsbury White, are responsible to a strong editorial committee, and in their foreword to the first number they state the objects of the journal. The pioneer work of Sir Henry Thompson, Sir Henry Morris, Mr. Hurry Fenwick, and Sir Peter Freyer laid the foundations of a school of British urology which is enlarging its scope and numbers every year, and includes workers not only in our own islands, but in Egypt, India, and the British Dominions. The promoters of the journal hope not only that it will unite British urologists in closer harmony, but that it will also interest workers in other countries, and its editors make a special appeal to English-speaking urologists in America. They hope to publish in every number one paper from the pen of an American author, and to assist visitors from abroad they propose to include in each issue a list of the chief British urological clinics. Other constant features are to be papers of interest to the general surgeon and general practitioner; a regular series of abstracts of current urological literature with an index conceived on modern lines; notes on developments of interest to urologists in biochemistry, chemotherapy, and radiology; and advertisements of novel and useful aids to the science. The first number contains seven original contributions: Mr. Andrew Fullerton describes drainage of the bladder through the perineum after suprapubic prostatectomy; Dr. P. J. Cammidge and Mr. H. A. H. Howard write on an improved method of

[2] British Journal of Urology. Published quarterly by Constable and Co., London, 6s. (annual subscription, £1).

titrating sugar in urine and blood; Mr. Victor Bonney contributes a paper on the gynæcological aspect of urology; Mr. Duncan Morison gives an account of experimental work on routes of absorption in hydronephrosis, carried out with dyes in the totally obstructed ureter; Mr. R. Gordon Craig and Mr. R. K. Lee-Brown write on the pyelographic diagnosis of renal tumour, and Dr. Maurice Meltzer, of New York, on the surgical aspects of polycystic disease of the kidney, while Mr. H. Temple Mursell relates the after-history of a case of nephrectomy for polycystic kidney. Other features are notes on interesting cases, urological hints for practitioners, biochemical notes, a copious body of abstracts, and an index medicus. The size of the publication is quarto; it is printed on highly glazed paper and illustrated with many excellent radiograms, photographs, and drawings. The coloured plate by Mr. Thornton Shiells, illustrating a hydronephrotic kidney with a suprarenal cyst in sagittal section, is an admirable example of lithographic work.

We wish our new contemporary many happy returns of the day.

IMMUNITY TO CANCER.

WHEN a small piece of a tumour is inoculated into an animal of the same species as that in which it originated spontaneously, the inoculated cells continue to grow and form a new tumour, the host supplying them with nourishment by means of the new blood-vessels of the stroma which it furnishes. It is possible experimentally to affect an animal in such a way that the inoculated tumour cells do not grow and do not form a new tumour. They remain alive for a few days and are then absorbed; they behave, in fact, just as normal tissue transplanted from one animal to another of the same species. This condition has been described as "immunity." It can be induced by injecting animals, before the inoculation of tumour cells, with normal tissues of the same species, and it is also induced when a transplanted tumour is made to undergo regression—for instance, by means of radium. When the phenomenon was first discovered 25 years ago, it seemed to have possibilities of therapeutic application. But exhaustive investigation by workers of the Imperial Cancer Research Fund served to disappoint these hopes. It was found that the blood of an "immune" animal had no toxic or lethal action on the implanted cells. If an animal bearing an implanted tumour was rendered "immune" by the injection of normal tissues, so that a second inoculation failed to take, the tumour inoculated before "immunisation" was not checked in its growth but continued to grow. Moreover, where a malignant new growth had developed spontaneously, injection of normal tissue failed to render the affected animal immune against the successful inoculation of its own tumour, and a spontaneous development of tumours was observed in "immunised" animals. The conclusion was inevitable, therefore, that the condition was not an immunity against cancerous cells, but rather an interference with the process by which the inoculated cells of one animal established themselves in another animal of the same species. It is not an "immunity to cancer" but an "immunity to the transplantation of cancer."

Work on this subject up to the year 1913 was reviewed by Dr. W. H. Woglom, of the Crocker Cancer Research Fund of Columbia University, in his book The Study of Experimental Cancer,[1] and in the March number of the *Cancer Review*[2] he gives us an account of the further investigations carried out between 1913 and 1928. His paper is a truly monumental contribution to scientific literature and has been prepared with the thoroughness characteristic of its author. The bibliography contains references to more than 600 papers and a study of the text makes it clear that Dr. Woglom has read almost all of these in the original. Nor is it a dry compilation of observations and conclusions recorded in the literature, for it is severely critical in tone. Of a number of conclusions which are reached the following may be quoted: "Immunity to transplantable tumours is a generalized refractory condition which appears to be entirely unrelated to other forms of immunity... The outcome of inoculation is determined by an interplay between the hostility of the host and the proliferative vigour of the implant, hence an absolute immunity does not exist... Resistance is effective during the first few days following inoculation, but entirely powerless against an established tumour. Nothing may accordingly be hoped for at present in respect to a successful therapy from this direction."

There is, however, an entirely different immunity to cancer which has been disclosed by the recent work of Dr. J. A. Murray and his colleagues. This immunity is directed not against the successful inoculation of cancerous cells but against the transformation of normal cells into cancerous cells. There are systemic factors which determine the susceptibility of an organism to the genesis of cancer. Some aspects of this problem were dealt with by Dr. Murray in the Twenty-fifth Annual Report of the Imperial Cancer Research Fund and their significance was discussed in our columns.[3] It is obvious that if further progress along these lines is possible it would be in the direction of preventing cancer rather than curing it.

ARTHRITIS DEFORMANS AND ACCIDENTS.

IN persons of rheumatic tendency slight injury may determine the localisation of the malady in a particular joint. At the recent meeting of the Royal Society of Medicine R. G. Gordon[4] emphasised the importance of trauma at the onset of cases of arthritis deformans, and it is common experience, too, that in the later stages of the disease, when patients become awkward and clumsy in their movements, a bad fall may follow a slight slip or trip, and fractures may result from a trifling cause. The formation of callus may be poor and union is sometimes much delayed. The association of accident with cases of arthritis deformans is of considerable importance when claims for compensation are likely to be made. E. Sonntag[5] lays down the following guiding principles for assessing these cases: (1) The accident must be well authenticated; retrospective claims should be viewed with suspicion. (2) The accident must have involved the joint concerned; if many joints are affected, an alleged accident probably had little to do with the disease. (3) The accident must be compatible with the injury, and sufficiently severe. The evidence is stronger when the claimant had to stop work and seek medical attention, and when there is injury to the skin and loss of blood. Effusion into a joint is not enough, since this often occurs in the course of the disease itself. (4) The time relationship must be considered, though here there is some latitude. The case is strengthened if the disease begins soon after the alleged accident. (5) A full investigation should be made for evidences of arthritis elsewhere. X ray examination is of special value, and should include comparisons with the corresponding joints of the opposite limb. Spondylitis is an important manifestation of arthritis deformans. It may be present to a gross extent without any disability; but symptoms may follow a slight injury, and often a severe hysteria is superadded. The statements of the patient and even of the witnesses must be thus sifted with care. Careful weighing of the evidence and a knowledge of the character and previous history of the claimant will usually enable a just decision to be made. It is in this type of case where medical experts may be approached by either side that a sharp conflict may result between

[3] THE LANCET, 1926, ii., 1139.
[4] THE LANCET, Feb. 23rd, 1929, p. 395.
[5] Klin. Wochenschr., 1929 viii., 474.

the views of those called in. Such conflict often brings medical evidence into disrepute in legal circles, and could doubtless in large measure be avoided by the general acceptance of a few basic principles such as those laid down by Dr. Sonntag.

THE PROGRESS OF CREMATION.

THE Cremation Society of England was founded in 1874, and 11 years later, after the famous Welsh Druid case, in which Mr. Justice Stephen held that it was not an offence to burn a dead body, the first crematorium in this country was opened at Woking for public use. Since that time progress has necessarily been slow, but the 1928 report of the Society shows that the number of cremations has been increasing more rapidly during the last few years than formerly. In 1928 there were 3436 cremations, as compared with 3265 for the previous year, and this represents nearly 30 per cent. increase on the previous five years' average. Twenty crematoria have now been established in the British Islands, the two latest being at Bristol and Ipswich. The erection of one in Guernsey has been sanctioned by the State Committee, and it is anticipated that the building will be opened for public use during the present year, whilst in Edinburgh also a crematorium is in course of construction. The Council of the Society notes that the growth of cremation is comparatively slow in many of the provincial centres, and it seems obvious that the provision of a crematorium is not enough; there must also be sustained local propaganda in its favour. During the year papers on cremation were read before a conference of the National Association of Cemetery Superintendents and at the Congress of the Royal Sanitary Institute at Plymouth, and the Central Council of Health Education has permitted the Cremation Society to attend the numerous Health Week exhibitions held in various parts of the country. Lectures to societies and guilds have also been arranged, but from the economic point of view little immediate result can be expected among the less wealthy classes of the community. At the same time the spread of knowledge to the masses may well enable some sort of industrial insurance scheme to be established in the future, so that cremation at death may be available to all who want it. In the meantime the Society is well advised to go on advocating cremation from the æsthetic side rather than the standpoint of economics and sanitation, for sentiment is probably the greatest obstacle to its universal adoption. Gardens of rest or remembrance have become ordinary adjuncts to a crematorium and represent a compromise with those who look upon the cemetery as a desirable feature of every town or city, on almost the same footing as a public park.

One practical point about cremation should perhaps be better known. If cremation is desired, it is necessary to inform somebody of this fact beforehand, and the will is not a suitable document for conveying the information as often it is not opened until after the funeral. The practitioner should bear this in mind if he is called upon to give advice about cremation—advice which more and more people are likely to ask of him.

AN OUTBREAK OF BRILL'S DISEASE IN ROME.

DURING the summer months, and more particularly in August during the last few years, a febrile malady has made its appearance in Rome. The pyrexia lasts 10–15 days, running a uniform course and is accompanied by an exanthem of somewhat indefinite character, and the disease is not contagious. A favourable termination is the rule. Outbreaks have occurred from time to time since 1920, but in 1927 and 1928 they became more numerous, 36 cases being notified in 1927 and 65 in 1928. The clinical picture corresponds to that of Brill's disease, which is held to be an attenuated form of typhus fever. The illness begins with fever and headache; the exanthem, which appears on the third or fourth day, takes the form of scarcely raised maculæ of various size from a millet seed to a lentil, round, reddish in colour, and frequently becoming petechial. The rash appears simultaneously on the trunk and limbs and after two days becomes diffuse over the abdomen and back and sometimes on the face. Among those attacked in 1927 and 1928 only three patients succumbed, two of them being of advanced age and suffering from chronic vascular and cardiac lesions. In the only case where death seemed entirely due to the disease histological examination of the skin showed the changes in the capillaries and the perivascular infiltration characteristic of typhus fever. Persons of all ages and both sexes were attacked. Epidemiological investigation revealed the fact that 95 per cent. of the patients lived in districts where a species of tick, *Rhypicephalus*, infected the dogs; some of the patients asserted that they had found these parasites on their bodies and exhibited cutaneous lesions strongly suggesting their presence. The close relationship between the disease and typhus fever was further indicated by the fact that the Weil-Felix reaction was positive in the majority of cases, at least in adults, when the blood was tested at a late stage of the attack or during convalescence. In children the Weil-Felix reaction was usually negative, possibly because in them the disease took a very mild form. Agglutination tests on patients affected by the outbreaks showed that the thermostability of agglutinins could not be regarded as a reliable method of differentiation between typhus fever and Brill's disease. The fact that in the Rome epidemic the virus was an attenuated one is associated, according to G. Pecori, of the Department of Public Health,[1] with the nature of the insect carrier of the virus. The louse is excluded as a carrier in Brill's disease, Marseilles fever, and the Rome epidemic. In the absence of lice, other insects must be implicated, and all the evidence seems to point to the dog tick. These ticks, which have a summer development cycle, are believed to carry the virus from unknown habitats to healthy persons. The modifications the virus undergoes during its passage through an intermediate host other than the louse may account for the changed epidemiological characteristics of the outbreaks which are transformed into a summer infection, sporadic, non-contagious, and running a mild clinical course. This attenuated form is called by Pecori "non-spreading summer dermotyphus." The appearance of dermotyphus of Brill's type in any locality does not in the least degree constitute an index of epidemic recrudescence of true exanthematous typhus.

CEREBRAL FORMS OF INFANTILE PARALYSIS.

ACUTE poliomyelitis may present itself clinically in many different ways but sooner or later as the disease evolves most cases reveal themselves as due to infection of certain parts of the spinal cord. Sometimes the virus seems to attack the higher parts of the nervous system such as the brain-stem, whilst the existence of frankly cerebral forms of the disease, leading, for example, to hemiplegia, was suspected as long ago as 1885 by Pierre Marie. The cerebral varieties, which may take the form of a pure encephalitis, often lead to difficulties in diagnosis, the physical signs depending very much on what part of the brain the virus attacks. Parkinsonian symptoms have been reported by Marinesco and the confusion of epidemic lethargic encephalitis with polio-encephalitis is by no means uncommon or surprising. Thus Mouriquand and co-workers[2] have lately described the case of a boy, aged 4, who died after only five days' illness which took the

[1] Il Policlinico, Practical Section, Feb. 4th, p. 151.

[2] Mouriquand, G., Bernheim, M., and Dechaume, J.: Jour. de Méd. de Lyon, Feb. 20th, p. 105.

form of an acute encephalitis. The child suddenly became weak in all his limbs and in his neck, with fever and curious chewing movements of his lower jaw. Lumbar puncture showed a clear fluid containing many lymphocytes with a normal sugar content and increase in the protein. The weakness in the limbs quickly became an actual paralysis, the pulse-rate grew very rapid, and the boy died. Onset of the disease was accompanied by somnolence from which he could be roused and there were no convulsions. The curious movements of the jaw were considered very similar to those sometimes seen in epidemic encephalitis and in lenticular degeneration, and it was this apparent affection of the regions of the basal ganglia which led to suspicion of lethargic encephalitis. Autopsy, however, showed quite clearly that this was a case of polio-encephalitis, and typical changes were found in the subthalamic region, in the floor of the fourth ventricle, and in the region of the origin of the trigeminal nerve. It is generally accepted that the morbid histology of the lesions in poliomyelitis and in lethargic encephalitis have points of clear distinction even if the parts of the brain attacked are the same, as in the case here related. What is not so readily recognised is that the clinical resemblance may be very close. The illness usually begins more suddenly in polio-encephalitis, with more evidence of an acute infection, while rapid onset of flaccid paralysis of one or more limbs is of help in diagnosis, though not, of course, present in pure encephalitis. Lumbar puncture and examination of the cerebro-spinal fluid is not of much assistance as the findings in the two conditions are similar. Mouriquand mentions the "neutralisation of the virus" test introduced by Netter and Levaditi, but this is in a sense retrospective only, for it depends on the fact that the serum of the convalescent polio-encephalitis patient will neutralise the poliomyelitis virus and render it harmless on injection into a monkey. Injections into monkeys of portions of the central nervous system from cases of polio-encephalitis reproduce the disease, but this is obviously useless in diagnosing the nature of encephalitis in a living patient and some biological test is wanted for this. A test of this kind would be especially valuable if such sera as that of Pettit, used extensively for poliomyelitis in many centres, is to be employed in the early stages of polio-encephalitis; and it is in these early stages that clinical diagnosis is so very difficult.

LATE CONGENITAL SYPHILIS.

AN elaborate study of late congenital syphilis is contributed by Dr. Walther Krantz, of Cologne, to one of the latest volumes of the work on general medicine now being issued under the general editorship of Prof. Brugsch, of Halle.[1] This form of congenital syphilis is now well recognised clinically. It may be a sequel to manifestations in infancy or it may appear, without previous indications of the taint, at the second dentition, at puberty, or even in early adult life. Indeed, the age-limit for the first appearance of signs of the disease is hard to set. Tabes and dementia paralytica are rare but well-known final stages. Full reference is made by the author to the work of Hutchinson to whom is due the clinical recognition of the malady and descriptions of the pathognomonic alterations in the teeth, interstitial keratitis, and disturbances of hearing, known as "Hutchinson's triad." The features of the malady may be grouped under four headings, but it is emphasised by Dr. Krantz that the incidence of the manifestations, with the exception of the very constant interstitial keratitis, varies. There is usually mental and physical infantilism of some degree; primary and secondary sexual development tends to be retarded. Certain stigmata are prominent. These include Hutchinson's teeth, Moon's dome-shaped molars, fissures and rhagades about the mouth, bossing of the calvarium, and depression of the bridge of the nose. The sundry cutaneous and mucosal lesions may be hard to differentiate from those of acquired syphilis. These stigmata are well illustrated in Dr. Krantz's article by photographs of cicatricial, destructive, and hyperplastic lesions of the face and skull. "Saddle-nose," "bull-dog nose," and "opera-glass face" are terms which appear under some of the pictures. Thirdly, the skeletal changes include Clutton's synovitis of the knees, usually but not always bilaterally symmetrical, and the sabre-shaped tibiæ in which the bone is increased in bulk by gummata and chronic osteo-periostitis. Lastly, the changes in the special senses are noteworthy. Interstitial keratitis, unilateral at first and then bilateral, appears during the second dentition. A haziness in the centre of the cornea quickly gives place to a general "ground-glass" effect. Visual disturbance and photophobia occur. Middle-ear disease is almost as constant as interstitial keratitis, but it takes place in earlier life. Dr. Krantz has supplied an adequate account of the disease in all its manifestations.

[1] Ergebnisse der Gesamten Medizin. By numerous contributors. Under the general editorship of Prof. Brugsch, Director of the Medical Clinic of the University of Halle. Vol. xii. Part 1. Berlin: Urban and Schwarzenberg. 1928. Pp. 294. M.35.

THE EPIDEMIOLOGY OF CHOLERA IN INDIA.

FROM bulletins of the Health Section of the League of Nations it is evident that India is the only part of the world where cholera still exists in epidemic form. Considering the heavy loss of life the disease causes there, it is surprising that so little attention has been paid in the past to its epidemiology. Fortunately this has been remedied to a certain extent of late years, owing to the better facilities given to the public health authorities. In making his well-known observations on cholera, Colonel W. G. King indicated clearly that the chief cholera season would follow closely the chief monsoon, and this "cholera clock," as he called it, is still found to beat true to time, the maximal incidence being reached six to eight months after the rains begin. The climatic factor is prominent among those considered in a recent review[1] of the subject forming one of the series of Indian Medical Research Memoirs. The analyses prepared by the authors are calculated from a large number of statistical tables and give only very generalised correlation coefficients to cholera and climatic factors, so that, in order to reach more definite conclusions, collected statistics will have to be re-examined in greater detail. The incidence of cholera in Assam and Bengal varies from that met with in other parts of India. Rainfall per se does not have that relationship with the incidence of cholera which has been demonstrated in other provinces; in fact, the correlation coefficients are all negative in sign. Hence, in Bengal rainfall and cholera are inversely relative, so that with the progress of the rains cholera practically disappears, and in these areas it may be said that cholera epidemics seem to be independent of weather conditions. In attempting to explain disease phenomena many factors have to be taken into consideration, such as weather, seasonal incidence, race distribution, sex, age, social status, and poverty; but in statistical analysis only a few of these can be dealt with, owing to the difficulty of obtaining the requisite data. Consideration of climatic factors alone has demonstrated the important part played by humidity, but we must assume that during the pre-epidemic phase some process goes on which leads to a progressive alteration in the equilibrium between parasite and host, and that an epidemic wave of mortality is propagated only when a certain limiting condition has been reached.

[1] The Epidemiology of Cholera in India. By Lieut.-Colonel A. J. H. Russell, C.B.E., I.M.S., Director of Public Health, Madras Presidency; and E. R. Sundararajan, M.A., Vital Statistician, Bangalore, Indian Medical Research Memoirs, No. 12, 1928.

PRINTERS AND PHTHISIS.

THE printing trade, employing roughly a quarter of a million persons, is nearly the largest of our factory industries. Those occupied, not only in this country, but also elsewhere, have long been known to have a high mortality from tuberculosis, but not from any other great cause of death. This curious combination of a low general death-rate with a high phthisis death-rate has been shared with the printers by the tailors and the bootmakers. The first report of the Medical Research Council was devoted to investigating this phenomenon among bootmakers, among whom, however, no specific trade risk was disclosed to account for it. In 1925 the printing trade invited the Industrial Fatigue Research Board to investigate the subject; and the result is now published of an intensive and painstaking inquiry made into the incidence of sickness, both from tuberculosis and from other causes, among different occupational groups within the industry. The long and intricate analysis of sickness records is by no means easy to follow, but the reader's task is simplified by a short preface outlining the method adopted and the results reached. Briefly this elaborate inquiry has left unanswered the question of the printer's liability to tuberculosis; certainly no trade risk has come to light. The printer's general sickness incidence, like his general mortality, is found to be low; yet his reaction to tuberculous infection, which is usually regarded as an index of general resistance to disease, is in excess. Consideration of the different occupational groups gives but little light and leading; the compositors, it is true, suffer in youth from an excess of general sickness and of tuberculosis, but they do not maintain this adverse experience after the age of 30. The warehouseman takes up the toll from the age of 30 to 50, overlapped by machine workers from age 40 to 60. No interchange of personnel takes place between these groups, which are separately recruited, to account for the facts observed. Possible explanations, regarding unfavourable working environment or the recruitment of the physically weak, are only mentioned to indicate lines for further investigation, particularly by medical examination of apprentices at entry. Few pieces of research have more clearly demonstrated the difficulty of acquiring adequate data from which sure deductions can be drawn about the connexion between morbidity and mortality. Yet it is in this field that knowledge is lamentably lacking. How can we pursue a sure line to attain resistance to this or to that infection, whether of tuberculosis or of influenza, unless we know the "sickness type" which tends to succumb? New methods of analysis, possibly quite diverse from those with which we are familiar for mortality records, are needed, and are being developed in America [2] as well as here; and appeal is being made particularly to industrial records to provide the facts required.

Sir Berkeley Moynihan, on his elevation to the peerage, has taken the title of Baron Moynihan of Leeds.

AT a meeting of the Fellows of the Royal College of Physicians of London held at the College on Monday last, March 25th, Sir John Rose Bradford was re-elected President.

WE regret to announce the death in London on March 23rd of Dr. Alexander Granville, who was at one time President of the International Quarantine Board of Egypt.

Mr. A. E. Cumberbatch, who died at his home near Rickmansworth, on March 23rd, was the first aural surgeon to St. Bartholomew's Hospital, holding office for the 25-year period from 1882 to 1907, and a life-long contributor to our knowledge of the surgery of the ear. He was in his eighty-second year.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCXC.—THE TREATMENT OF VULVAR AND ANAL ECZEMA.

PART I.*

Pruritus and eczema of the vulva and anus are amongst a group of distressing maladies for which even in these outspoken days many women seek no medical aid, preferring to suffer in silence. One life-long friend never mentioned to anyone the irritation which had troubled her since the age of 17, until she found a growth developing in her sixty-fifth year; this was malignant and was excised just in time. Excluding uncomplicated "eczema marginatum" I have notes of over 130 cases cured in private practice during the past 18 years. I have recently tried to trace them all, but many letters were returned undelivered. Fifty-two reported no relapse; 12 reported slight recurrences with which they could deal unaided; five cases return every few years because the causal agent cannot be permanently eradicated.

Pruritus of the anus may be severe, even when little abnormal is visible on examination. If it is progressive the perianal tissue becomes swollen and sodden, with thickened ridges and fissures, and the eczematous condition spreads to the buttocks and forward to the vulva. When the intergluteal fold is involved a most painful fissure usually follows. Pruritus and eczema of the vulva takes many forms, varying from the milder types which show a scarcely perceptible hyperæmia, or a chronic white leathery appearance over the inner aspect of the thickened labia, to the enormously swollen and painful condition which is seen when the eczema is fissured and œdematous and extends to groins and intergluteal fold. Even in the mildest cases the irritation may be intense, leading to ungovernable scratching, especially at night, when self-control is diminished. The patients become depressed and suicidal, not only from lack of sleep, but from despair over the failure of most local applications to bring about more than a slight alleviation of their misery.

Causation and Prognosis.

With eczema or pruritus ani it is usual to find some degree of constipation, which may be or may not be accompanied by hæmorrhoids. Even when there are no bleeding piles, the examining finger frequently encounters a constriction just within the rectum. When this is present, and also in the capillary type of hæmorrhoids, the prognosis is good. Treatment with the high-frequency metal or vacuum electrode causes disappearance of these forms of piles, and coincidently the irritation improves. On the other hand, the prognosis is bad with deeper-seated piles and when there is a small muco-cutaneous pile at the posterior margin of the anus. These do not respond except to surgery or diathermy, and till they go the pruritus or eczema tends to relapse. The presence of worms is a not infrequent cause of anal irritation in children, but is not often a cause in adults. Pediculosis is a rare cause in private practice. Colitis and diarrhœa, the latter especially in children, are common exciting causes. The general health and whole intestinal condition must be dealt with before the anal condition will cease to relapse. Psoriasis may affect the ano-genital region, and become eczematised; it is very rebellious to treatment. Only within recent years have I become aware that the leakage from the rectum of mineral paraffin preparations can set up intense irritation, spreading even to the vulva and vagina. Once this is known it is easily dealt with; probably this was the unrecognised cause of several relapses, for which I could find no reason in previous years.

* Part II. will appear next week.

Cases are sometimes seen with slight discharge, but marked hyperæmia extending a short way up the vagina, with continual relapses until the husband undergoes treatment. Castellani has drawn attention to a fungus which he found in 11 out of 54 cases of anal pruritus. Even with severe pruritus ani nothing may be seen, or only tiny infiltrated red patches. When scratched these become secondarily infected with streptococci. This condition often has periods of remission and is very obstinate.

When the eczema affects chiefly the vulva the prognosis and treatment of the case depend upon the removal of the cause, and this is often hard to trace. One should note whether the irritation is restricted to the vulva, whether it extends up the vagina, or to the groins, thighs, and pubis, or whether it extends to the rectum and intergluteal fold. Eczema marginatum, due to the *Epidermophyton inguinale*, has become much more frequent since the war. Advice is usually sought in the early stage, when red patches, slightly scaly, are beginning in the groins and spreading to the genitals and thighs, even to the abdomen. The sharply defined margin on the skin is so characteristic that one rarely has to examine for fungus in order to make the diagnosis. If the disease is not dealt with early the vulva becomes thickened and eczematised. The prognosis is excellent. Leakage of paraffin from the bowel can cause intense vulvovaginal irritation with hyperæmia, and is usually unsuspected when the anus and perineum remain healthy, as frequently happens. Diabetes is a well-known cause of severe eczema of the vulva, but is not so frequently met with as other causes in dermatological practice. When only the genital region is affected the condition is usually due to infection from the bladder or the vagina. In young girls vaginal discharge is often due to *B. coli* and the local condition is often difficult to deal with.

A vaginal or a cervical discharge is, I believe, the most common cause of intractable eczema of the vulva in the adult. Sometimes this discharge is quite at the entrance of the vagina, and is then usually due to *B. coli* or the gonococcus. A catheter specimen of the urine should be taken and the condition of the urethra noted; a slight urethral discharge is easily overlooked. When the vagina seems clear, except for a slight milky discharge, it is not safe to assume that the source of the irritation is not a uterine discharge. Even when the patient denies the existence of any discharge, after the introduction of a speculum an erosion of the cervix with thick muco-purulent discharge is often found, and the reason for the external irritation is at once obvious. For long I did not recognise the importance of a scanty amount of clear mucus without any erosion. Within recent years I have had convincing proof that this scanty clear mucus is capable of causing marked irritation and eventually eczema. This clear discharge is usually found to contain streptococci, but may also show gonococci. Treatment of the discharge in such cases alleviates, and return of the discharge causes renewal of the irritation. In some cases it is most puzzling to trace any causal agency. One healthy young woman who had a continually relapsing eczematous patch near the anus, but an otherwise healthy skin, remarked one day that the irritation vanished when she was at the seaside or in mountain air. This put me on the track, and on inquiry regarding dietetic excesses, I found that when at home she indulged freely in sweets and chocolates. One is apt to forget that patients do not follow out advice on diet for more than a restricted period of time; in chronic and relapsing cases inquiry must continually be made as to whether all directions are still being followed.

A rare cause of intense irritation is leukoplakia vulvæ. The mucous membrane shows in the early stage hyperæmia, telangiectases, and bluish, atrophied, or milky-white patches. The irritation does not respond to the usual treatment. Fissures appear from which later on malignant growth develops. In the final stage all the parts become smooth, atrophied, and contracted. Kraurosis vulvæ is often confused with the late stage of leukoplakia, but in the former the urethra and vestibule are always involved; there is more soreness than pruritus, and no malignant tendency. Four cases of leukoplakia vulvæ which I have seen I passed on to be dealt with by surgeons. One case, which I believed to be an early leukoplakia, with definite hyperæmic patches, telangiectases, a few bluish-white patches, and severe irritation, became completely cured when I stopped the strong disinfectant vaginal douches which the patient was in the habit of using daily, from mistaken ideas of hygiene. Four years have passed and there has been no relapse.

General Management.

Strict attention must be paid to rules of hygiene. No constipation dare be allowed, especially when there is anal irritation. The general health must be attended to; and sufficient sleep must be ensured. Of prime importance is the guarding of the parts from further contamination with the infecting agent. One reads how the parts must be cleansed *after* contamination by discharge, urine, or fæces. So far as I know no authorities advise precautions to prevent sources of contamination from touching the areas they pass over. The labia and the perianal region should be freely smeared over with oil or vaseline before the passage of the urine or stools, then gently cleansed and the selected ointment substituted. For anal cleansing soap and water can be used when the part has thickened leathery ridges. Care must be taken to keep the intervening grooves clean. Paraffin preparations should be forbidden, lest leakage lead to constant reinfection and impossibility of keeping the parts clean. Hæmorrhoids must be dealt with. All sources of vaginal discharge must be stopped, either by douching, pessaries, or best of all, by ionisation of the infecting source—cervix or vagina. For young girls diathermy is on trial and promises well; it can be administered per rectum. The urine must be tested for sugar, and a catheter specimen taken to make certain there is no urinary infection. Even in *B. coli* pyelitis, however, it must be remembered that the organisms may be absent at one period of the day, abundant at another. Hence a negative report must be compared with the history and the aspect of the patient before it is accepted. The diet must be regulated according to the individual needs. In some cases tea and coffee, and in almost all cases alcohol, excess of sugar and particularly of chocolate aggravate pruritus, especially anal pruritus. Tobacco aggravates some cases. Abundance of water, fruit, and green vegetables suit the majority of patients, but not those who have spasmodic colitis. I often find that thyroid and calcium salts, when indicated, hasten the cure, especially at the menopause.

Sleep must be ensured, and this may tax all the resources of the physician. With a severe case the first week of treatment is full of anxiety; every sedative lotion and ointment may have to be tried in succession when the patient is of the doubting, nervous, uncontrolled, or sleepless type. It is essential to impress upon the patient that she must dab the applications on, never rub them in. Every scratching or rubbing throws back the cure so many days, even so many weeks. Again and again I have seen a case almost well; after a vigorous scratching when half awake the labia have swelled up to four times their size on the previous night. If irritation is unbearable tell the sufferer to press hard, and till the crisis passes hold stationary on the part either a hot or cold compress of 1 in 50 carbolic or weak solution of Jeyes' fluid or other tar preparation. No source of local friction must be permitted. Women should preferably wear open knickers. No under-linen must rub against and fray the skin or mucous membrane. Friction with the clothing is a potent cause of irritation and even of reinfection when the patient cannot carry out frequently during the day careful protection, cleansing, and local applications.

BLOOD STANDARDS.

A CRITICISM OF THE GENERALLY ACCEPTED NORMAL VALUES.

By S. C. DYKE, D.M. Oxf., M.R.C.P. Lond.,
CONSULTING PATHOLOGIST TO THE ROYAL HOSPITAL, WOLVERHAMPTON.

"In healthy males the average number of the red cells is 5,000,000 per c.mm., in females, 4500,000 per c.mm."

"In health there are five million red corpuscles (four million five hundred thousand in the female) per cubic millimetre."

THE quotations are from the latest edition of a standard text-book on the blood and from a recently published text-book on surgical pathology. The figures given above, and which have been repeated from text-book to text-book, are derived, so far as can be ascertained at this distant date, from the work of Vierordt in 1852 and Welcher in 1854. Rivers of polysyllabic terms for the same cells have poured through the publications on hæmatology since that time, but it is a tribute to the essential and solid conservatism of the minds of workers in this field that these figures, based on the examination of four subjects, should still hold the field.

The "Normal" Red Count.

Bie and Möller[1] working in Denmark, who published their results in 1922, appear to have been the first to make a serious attempt to arrive at what may be considered as a "normal" for the number of red cells in the blood of adult males of the white races. Gram and Norgaard[2] also working in Denmark, followed them a year later, but the total number of subjects investigated by these Danish workers was only 17. Osgood and Haskins[3] working in the state of Oregon, U.S.A., first dealt with the problem on an extensive scale, their results being based on the examination of the blood of 137 subjects. Osgood's results were published in 1927 and formed the basis of an annotation in THE LANCET at the time. All these workers arrived at closely similar figures, the average for all being 5,410,000 red cells per c.mm. of blood.

With a view to ascertaining whether or not residence in a hot climate is associated with any variation in the number of red cells from that found in dwellers in the temperate zone, Wintrobe and Miller[4] have recently investigated the blood of 100 males between the ages of 19 and 30 resident in New Orleans. These workers found an average figure of 5,850,000 red cells per c.mm.; this finding is in direct contradiction to the very general assumption that in members of the white races residence in a hot climate tends to produce an anæmia, this confirming the opinion of Balfour[5] that the so-called tropical anæmia is apparent rather than real. Two of the authors' subjects showed the unusually high red cell count of 7,000,000 per c.mm., a fact which tended to raise their average; taking all the figures into consideration they are inclined to doubt that residence in a hot climate has any effect on the number of red cells even in the direction shown by their data, and to regard 5,500,000 per c.mm. as constituting a reasonable "normal" for members of the white races, at any rate so far as the zone of climates included between 30 and 54 degrees of north latitude is concerned.

The "Normal" Hæmoglobin Percentage.

Most of the standard text-books on the blood remain dumb on the subject of the average amount of hæmoglobin in the blood of healthy subjects; the one referred to above gives no fewer than nine methods for the estimation of hæmoglobin percentages without affording any information as to what may be regarded as constituting 100 per cent. Makers of hæmoglobinometers for the most part likewise refrain from providing information on this important point. As Wintrobe and Miller remark:—

"it is not generally known that the Sahli instrument accepts 17·2 g., per 100 c.cm. of blood as 100 per cent., while the Dare is based on 13·8 g. as the equivalent of 100 per cent.; the Newcomer standard is 16·92 g., whereas the Tallquist scale is set on a basis of 15·8 g. This wide variation in the accepted standard is merely a reflection of the inaccurate basis on which these figures have been calculated."

In view of the fact that the hæmoglobin percentage of the blood varies with age, sex, altitude, and even, as shown by Dreyer and his co-workers,[6] with the time of day, it is obviously difficult to establish a "normal" standard, and calculations based on any such supposed normal must be accepted with due reservations. The figures of both Osgood and of Wintrobe and Miller, however, show variation about a mean somewhere in the neighbourhood of 16 g. per 100 c.cm., with averages of 15·88 and 15·87 respectively. All these workers agree that, given due consideration to the wide variations met with in healthy subjects, 15·88 g. per 100 c.cm. may be regarded as an arbitrary but convenient "normal" for the hæmoglobin of the blood of adult males. In the calculation of the colour-index, some reasonable normal standard is particularly necessary; it is obvious that very different indices will be obtained on the same blood according as to whether 13·8 or 16·92 g. of hæmoglobin per 100 c.cm. of blood be regarded as 100 per cent., and that consequently users of the Dare hæmoglobinometer will always obtain a higher colour-index than users of the Haldane or Newcomer instruments. For purposes of this calculation certain advantages attach to the use of 5,000,000 as the "normal" number of red cells per c.mm., and Osgood has suggested that this convention should be retained and that figures for the hæmoglobin should be expressed as the number of grammes per 100 c.cm. of blood calculated to a red cell count of five millions; for this figure he suggests the term "hæmoglobin coefficient." The figures for the hæmoglobin coefficient obtained by all those who have gone accurately into the matter vary between 13·34 (Bie and Möller) and 15·57 (Osgood and Haskins); the variation about the mean is in the neighbourhood of 14 and the average of all the averages 14·29. Wintrobe and Miller draw attention to the fact that before accurate colour-indices can be calculated the normal average hæmoglobin coefficient must be established, and that when established this is the figure which should be used as 100 per cent. in the various clinical hæmoglobinometers. Failing this, it is in the highest degree desirable that all hæmoglobinometers sent out from the makers for clinical use should bear in plain figures the numbers of grammes of hæmoglobin per hundred cubic centimetres of blood representing their particular 100 per cent. Workers could then make their own corrections. In the absence of these corrections misleading results may be obtained.

The "Normal" White Count.

"Normals" for the white cells of the blood are even more difficult to assess than for the red cells. It has long been known that these are subject to diurnal variations, and it was at one time supposed that these variations depended upon digestion, a belief still largely held in spite of the investigations of Sabin[7] and her co-workers and of Shaw,[8] who have shown that the ingestion of food has no effect upon the number of leucocytes in the circulating blood, but that in normal persons there is a rhythmic diurnal rise and fall in their numbers, a decrease in the early part of the day being followed by a rise as the day proceeds. Recently Smith and McDowell,[9] working at South Hadley, Massachusetts, have investigated this rhythm during the course of menstruation in normal women and have been able in the first place to confirm its independence of the ingestion of food and in the second to establish that it is unaffected by physiological menstruation. For the white cells, then, it remains impossible to establish any one figure which can be

regarded as "normal," but it is obviously necessary that in taking series of white cell counts from the same subject the specimens should be taken at the same time of day.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Research in Children's Diseases.

THE research work of the Royal Glasgow Hospital for Sick Children has been well known for several years. At the annual meeting Lord Maclay, as chairman, called attention to the fact that the directors were making an appeal for a research fund of £20,000. This is a very striking departure in hospital appeals. It shows that, at last, the fundamental value of research is becoming better understood by the lay public. Dr. A. S. M. Macgregor, medical officer of health for Glasgow, strongly supported the appeal for a research fund, adding that facilities for research were the very life-blood of an institution of that kind, and that no more important investigations could be undertaken than those concerned with the biology of child life and with the prevention and treatment of children's diseases. He knew of no institution whose influence had so permeated the whole child welfare movement or whose work had so influenced current views on the prevention and treatment of the affections of childhood. On its medical side a stream of valuable contributions had been added to their knowledge of the feeding and nutrition of children, the factors which influenced growth and development, rickets, and other affections. On the surgical side the hospital was identified with the treatment of orthopædic defects and with sound schemes for better methods of prevention and treatment throughout Glasgow and the west of Scotland. He hoped that the hospital would be regarded as the centre from which the most scientific and most up-to-date information could be obtained as to the health, welfare, and treatment of infants and children under 13 years of age.

The Future of Medical Practice.

Dr. Parlane Kinloch, Chief Medical Officer of the Department of Health for Scotland, in a recent address at Glasgow, said he was convinced that an improvement in the medical service depended mainly on a continued improvement in medical education. The improvement in medical education had failed to keep pace with the vast increase in medical knowledge, and it could not hope to do so until the preventive conception dominated completely the whole system of medical teaching. The artificial division between preventive and curative medicine could no longer be recognised. The treatment of one disease was the prevention of other diseases. It might be accepted that an adequate medical service would not be available until the training and work of the general practitioner and the statutory medical officer were so coördinated that the general practitioner was re-established in his position of full responsibility as family doctor, responsible for watching over the family health, responsible for the prevention of disease, and utilising for that purpose the whole of the official machinery that local authorities had provided. If this great achievement was to be realised the medical student must be so educated as to be fit for his increased responsibilities. And if he was to be properly educated the present bounds within which medicine, surgery, and midwifery were taught must be extended. The present medical training schools would have to be expanded so as to incorporate within them the great public medical services so that there should be an interlocking and interchanging of all their activities for the purposes of medical education.

VOLUNTARY AND MUNICIPAL HOSPITALS UNDER THE COMING LOCAL GOVERNMENT ACT.

REPORT BY KING EDWARD'S HOSPITAL FUND FOR LONDON.

IN January last a Special Committee was appointed by the Prince of Wales, as President of King Edward's Hospital Fund for London, to consider what steps should be taken, during and after the passing of the Local Government Bill, to maintain the existence of the voluntary hospitals as an essential part of the hospital system. This Committee, under the chairmanship of the Right Hon. J. H. Whitley, had for its members Viscount Knutsford, Sir Arthur Stanley, Sir John Rose Bradford, P.R.C.P., Sir Berkeley Moynihan, P.R.C.S., Right Hon. Hugh P. Macmillan, K.C., Sir Herbert Cohen, Sir Edward Penton, Sir Cooper Perry, M.D., and Mr. V. Warren Low, F.R.C.S. A memorandum, dated March 22nd, has now been issued [1] by the Committee dealing with the general principles of the Bill as they affect the whole country, and not specially with the problems peculiar to London.

The fundamental principle laid down in the memorandum is that there should be the maximum of efficient service for the sick and suffering. For this purpose there must be coöperation, not competition or overlapping, between the voluntary hospitals and the municipal hospitals. The Committee regard this as being essential to the full efficiency of both branches of the hospital service. They desire that the municipal hospitals should be brought to a high standard. But if this is done in such a way as to lead, directly or indirectly, to the disappearance of the voluntary element in the hospital service, this would mean in their belief the disappearance of something which is essential to the maintenance of that standard; and in the end there would not be the maximum of efficient service for the sick and suffering. The voluntary element in management and finance produces an atmosphere which, in this country at all events, is particularly favourable to hospital service. It allows, even in large institutions, the freest possible scope for the personal factor in the work of doctors, nurses, and administrators, on which the well-being of the patients largely depends. It affords the medical men, including the leaders of the profession whose services elsewhere command a remuneration proportionate to their long training and great skill, the maximum of freedom to use all their faculties, aided by the resources of the hospital, for the advancement of medical science. The lay management is in the hands of individuals, often of high capacity in their ordinary spheres, who have voluntarily undertaken it because they are personally interested in it, and who are becoming more and more representative of all classes. The work of the hospital is the sole business of the governing body. All concerned are encouraged to take a personal interest in the welfare of the patients. The hospital is in direct touch with the outside world, and has a peculiar sensitiveness to public opinion which is very valuable in connexion with the treat-

[1] Relations between Voluntary Hospitals and Municipal Hospitals under the Local Government Bill. Published for King Edward's Hospital Fund for London by Geo. Barber & Son, Ltd., 23, Furnival-street, Holborn, E.C.4. Price 3*d*. net; 4*d*. post free.

ment of the sick. As a result of all these causes, the voluntary hospitals have acquired a tradition and a prestige which, when combined with the free scope which they offer to initiative, have attracted to their service men of conspicuous ability, both medical and lay. It has been in the voluntary hospitals that the highest standard of medical and surgical work has been developed, and it has been with the standard of the voluntary hospitals before them, and with the aid of medical men trained in the atmosphere and spirit of those hospitals, that the recent improvements in many of the poor-law infirmaries have taken place. An efficient and adequate hospital service can be created, not by converting the voluntary hospitals into official institutions, but by developing municipal hospitals in coöperation with, and under the influence of, a vigorous voluntary hospital system.

Finance and Accommodation.

From the point of view of finance and accommodation, the contribution of the voluntary hospitals is also of great importance. Taking Great Britain as a whole, the number of hospitals is 930, with about 64,000 beds. The total of voluntary gifts is approximately £9,000,000, including receipts from hundreds of thousands of contributors through weekly workshop collections. Of this £9,000,000, over £6,000,000 is for annual maintenance alone, and more than £2,000,000 for capital purposes. But the destruction of the voluntary hospitals would represent the loss of far more than this: these millions would not be the only charge on public funds, because of the great amount of voluntary work, both lay and medical, which accompanies them. In the hospital service, therefore, both municipal and voluntary hospitals should be essential parts, and should be recognised as such by the public, both as ratepayers providing that part of the service which is best provided out of the rates, and as voluntary contributors providing through the voluntary hospitals those special features which depend on the maintenance of voluntary management and voluntary finance.

The memorandum goes on to make a number of practical suggestions for securing the best form of coöperation in the future. There should be continuous consultation between the authorities responsible for the rate-supported and the voluntary hospitals, respectively. This is now provided for by the new clause, introduced into the Bill in the House of Lords, which runs as follows:—

"The council of every county and county borough shall, when making provision for hospital accommodation in discharge of the functions transferred to them under this part of this Act, consult such committee or other body, if any, as they consider to represent both the governing bodies and the medical and surgical staffs of the voluntary hospitals providing services in or for the benefit of the county or county borough, as to the accommodation to be provided and as to the purposes for which it is to be used."

The Committee propose that there should be a Standing Joint Hospitals Conference in each area, composed of equal numbers of representatives of the appropriate committee of the county or county borough council and of representatives of the voluntary hospitals, including both laymen and medical men. The King's Fund is considering the best method of securing this representation in London. As regards the rest of the country, the British Hospitals Association through its regional committees is, at the suggestion of the King's Fund, taking the necessary steps. The functions of these conferences should be advisory, not executive. One of the principal functions of the joint conference would be to consider the hospital needs of the area, and the question which of these needs could best be supplied by the voluntary hospitals and which by the county hospitals.

Staffing and Equipment.

The memorandum also discusses the staffing and equipment of the two kinds of institution. It suggests that, where local circumstances permit, the municipal hospital service should be linked up with the voluntary hospital service through the appointment on the staffs of the municipal hospitals of consultants who are experienced in voluntary hospital work, so that the same spirit may influence both. On the question of the classification of patients, it suggests that great difficulties would arise if any attempt were made to lay down definite rules differentiating classes of patient, and allocating them to different kinds of institutions, either according to the nature of the ailment or according to social status, and that whatever form and degree of classification is found to be desirable will be developed in actual practice.

MEDICINE AND THE LAW.

Cockroaches in a Flat.

A LADY who was tenant of a flat at the Marble Arch succeeded in obtaining £481 damages from her neighbours on the ground of their encouragement of cockroaches on a lower floor and the consequent invasion of her premises by swarms of these unwelcome insects. She claimed that she had been unable to sleep at night, that her health had been affected, that her rooms and curtains had been damaged, that she had lost the amenities of her flat, and had suffered from the work done in the attempt to exterminate the insects and from the smell of disinfectants. Her claim included an item of £110 special damage for repairs, materials, cleaning, and medical attendance. Her medical attendant, Dr. Philip Dennis Scott, described her condition a few days before Easter, 1928. She was excited and nervous and she complained of sleeplessness owing to the presence of the cockroaches. Later he found marks on her neck which resembled bites; in the autumn she developed dermatitis and was sent to the St. John's Hospital for Diseases of the Skin. It was put to him in cross-examination that dermatitis might have been caused by the use of sulphur ointment, but this ointment, he said, was not used till the dermatitis had appeared for some weeks. Dr. William Griffith, who had attended the plaintiff at the hospital, attributed the dermatitis to the nervous upset which she had suffered. Expert evidence was given on the subject of cockroaches. The plaintiff's claim alleged that the insects were of the species known as *Blatta orientalis*. Mr. Ernest Crabbe, Fellow of the Entomological Society of London, called on behalf of the defendants, said he had been to the premises and discovered specimens of *Blatta orientalis;* he handed the judge a box of them. He did not think these insects could bite and pierce the human skin, but they ate bed-bugs. Both cockroach and bed-bug came to this country in 1583. Cockroaches, he said, were practically omnivorous; they would eat each other, organic refuse, or, preferably, sweet things. He regarded this as an "ordinary case of cockroach infestation."

The plaintiff's claim was for damages for nuisance or alternatively for negligence—nuisance in that the defendants had so used their property as to cause her substantial discomfort, negligence in that they had failed to take reasonable precautions of care and cleanliness or to appreciate the consequences of the accumulation of refuse in the café below her flat. She said the defendants were owners of the café premises while used as a café and were occupiers of those premises after they ceased to be so used. The jury's detailed answers to a series of questions framed by the judge will indicate the steps by which the plaintiff's claim was established. Did a quantity of animal or vegetable refuse remain on the café premises between certain specified dates?—Yes. Was such refuse unusual in quantity?—Yes. Did it constitute a nuisance in the circumstances?—Yes. Did the refuse cause or substantially contribute to the invasion of the flat by cockroaches?—Yes. There were other findings on the aspect of negligence, the alternative to nuisance. But the findings as to nuisance were sufficient. The question whether the refuse was unusual in quantity is significant. There was an interesting

decision in 1914 on proceedings against a market gardener from whose manure heaps came smells and flies to the detriment of his neighbours. An injunction was granted against him because, though it is usual for manure to be used in market gardening, what this particular market gardener had done was regarded by the court as something quite beyond ordinary market gardening. Similarly, it is natural that there should be some accumulation of animal and vegetable refuse in premises where the business of a café is carried on. It is the excessive or unusual accumulation which gave the plaintiff the right to damages. The café, it was explained, has now been demolished, the Regal Cinema having been erected on the site.

Appeal against a Death Sentence.

Dr. Benjamin Knowles, who until last October practised as a medical practitioner in the Bekwai district of the Gold Coast and was employed as medical officer in charge of that district, was arrested on Oct. 21st on a charge of shooting his wife with a revolver. A month later he was found guilty of murder by the Acting Circuit Judge (who tried the case without a jury) and was sentenced to death, but the sentence was commuted by the Governor of the Gold Coast. Dr. Knowles has petitioned the Judicial Committee of the Privy Council for leave to appeal against the judgment of the local court, and the Judicial Committee has granted him leave to appeal. The next stage therefore is that he will appear before the court in Downing-street in the submission of the appeal itself. The facts as stated on the recent proceedings were that Dr. and Mrs. Knowles gave a luncheon party at their bungalow on Oct. 20th at which various Government officials were present, that later (about two hours after the guests had left) Mrs. Knowles, being then in the bedroom with her husband, received a revolver wound of which she died two days afterwards in Kumasi Hospital, and that in a dying deposition she declared that the shot had been accidentally caused by her getting up out of a chair on which the revolver had been placed. The Acting Circuit Judge said he had to decide whether the firing was an accident or whether Mrs. Knowles's dying statement was a generous woman's falsehood; he described the evidence as confusing, but overwhelming, and said there could be no doubt of the guilt of the accused. Dr. Knowles's petition for leave to appeal was based on the grounds that the local court had no jurisdiction to try him without a jury, that there was no reliable evidence on which a capital conviction could safely and justly be founded, that the judge failed to give effect to the paramount rule of law that the onus of proof was on the prosecution, and finally that the case should have been referred to the local Supreme Court for trial with a jury. The tribunal before which Dr. Knowles was tried was the Chief Commissioner's court. Its procedure is governed by the Ashanti Administration Ordinance (No. 1 of 1902) whereof one clause says that no accused person may have the services of a barrister and solicitor. Another clause says that the court is to follow the procedure of the Supreme Court of the Gold Coast so far as practicable and so far as local circumstances permit. It does not appear that the judge made any statement that trial by jury was impracticable or impossible owing to local circumstances. It will be a matter for argument on the appeal whether any circumstances could bar an Englishman's right to trial by jury when accused on a capital charge and whether, if the trial was legal in view of the Ordinance, the Ordinance itself is valid. No reference was made during the recent proceedings to a subsequent Ordinance which is understood to have modified (by way of statute law revision) the wording of the Ordinance of 1902. The Privy Council was inclined to regard as meagre the information before the court. One might add, perhaps, that service in an out-district in the Gold Coast seems to be exposed to risks which strike an Englishman as strange, and that the Government does not seem to have been at any pains to assist the defence of one of its servants.

Correspondence.

"Audi alteram partem."

THE USES OF ULTRA-VIOLET LIGHT.

To the Editor of THE LANCET.

SIR,—As your leading article points out, it is a matter of medical history that though ascertained scientific facts may be the truth, they are not necessarily the whole truth. When the Medical Research Council state that "their prolonged researches . . . give no scientific reason at all to suppose that the treatment of rickets is better effected by ultra-violet rays falling on the skin than by the direct provision of the necessary food values," they are doubtless stating the truth according to their lights. But those of us who have worked at light clinics in industrial districts and who know so well the practical working conditions will be profoundly unconvinced. We remember the wretched specimens of infants with digestion impaired, unable to tolerate cod-liver oil, and the ignorant, careless, or harassed mothers who could not be depended upon to give it. We remember how often cod-liver oil failed us under those conditions, and how, on the other hand, ultra-violet light effected not only a rapid cure of rickets, but a wonderful uplift in general health. I, personally, tried dietetic and hygienic measures under these conditions in the treatment of hundreds of cases of rickets at Motherwell Child Welfare Centres from 1919 to 1924, and I freely confess that the adverse conditions proved too much for me. Success was comparatively negligible. From 1924 to 1925 I had a series of cases which had practically failed under this treatment respond rapidly to ultra-violet light. In 1925 and 1926 when the light clinic was organised I treated 121 cases to a conclusion and easily and rapidly achieved satisfactory radiographic cure in 95 per cent., as well as astonishing improvement in general health in the vast majority. Of course, I know that all this is not "scientific." But it was all that I had time and opportunity to do in that unfortunate area, and the degree of success achieved was sufficiently remarkable to satisfy all concerned.

I believe I am not by any means alone in this experience. Indeed, my observations, which might otherwise have been published in much greater detail than they have been, were anticipated by the appearance of Dr. Katherine Gamgee's book on "Artificial Light Treatment of Children" in which case-histories in rickets are given, showing precisely similar results to mine. The Medical Research Council state that reports submitted from artificial light centres "exhibit much variation of opinion," but if these reports are studied with discrimination, I believe that no appreciable difference of opinion will be found as regards (1) the rapid cure, even under adverse conditions, of the bony lesions in active rickets, and (2) the remarkable improvement obtained in general health in such cases, including such factors as improvement in muscle tone and associated activity in waking hours, the disappearance of apathy, fretfulness and sleeplessness, and the appearance of happiness and well-being.

The reports on the London children quoted by the Council deal, of course, with a different class of case altogether, but there is no clear indication of this distinction in the Council's statement. On the basis of these two limited investigations and of current laboratory findings, the Council seem prepared to condemn artificial light centres for rickets as unnecessary and about 50 times more expensive than alternative methods of treatment. In their estimate of cost they appear to have entirely overlooked the fact that many children can be treated together round the lamps, thereby making the cost per case very low. Huldschinsky, who made the great dis-

covery of the cure of rickets by ultra-violet light, stated that "a single quartz lamp rationally employed can cure annually some 1000 rickety children." But much more serious than any question of cost is the fact that the Council ignore the almost unanimous body of opinion in favour of light treatment of active rickets, expressed by clinic workers who have personal experience of it, at any rate, in the industrial districts of the north. It is a gesture which, if successful, would deprive such workers of a therapeutic armament which, in their hands, has been productive of immense benefit to child life, and such a thing at this late stage is unthinkable.

I am, Sir, yours faithfully,

H. STANLEY BANKS,
Medical Superintendent, Isolation Hospital and Sanatorium, Leicester.

March 24th, 1929.

To the Editor of THE LANCET.

SIR,—A considerable part of the report of the Medical Research Council will be endorsed by the whole medical profession. The flooding of the market with cheap ultra-violet apparatus, which is useless for therapeutic purposes, but which is capable of electrocuting the user (according to a recent inquest) in five different ways; the absurd claims made, such as the value of titanium rays, and the employment of ultra-violet in conditions in which it cannot possibly do any good, cannot be too strongly condemned. There is a good deal of the report, however, which is open to criticism.

Referring to Dr. D. Colebrook's and Dr. H. Mackay's investigations into the value of ultra-violet treatment in children and the negative results, the report states, "The Council are aware of no properly controlled experiments which have been made elsewhere to set against these two series." Sir Henry Gauvain has published such reports. He describes tests carried out in children in the same ward and therefore under identical conditions, and also tests on similar types of children but in different institutions. The Council appears to have overlooked the opinion of its other investigator, Mr. W. S. Duke-Elder. This is his opinion, after dealing with tuberculous diseases of the eye:—

> "Closely allied in its incidence and as dramatic in its response is phlyctenular keratitis. Especially does this apply to children and the typical phlyctenular child, pale, fretful, irritable, and distressed with photophobia, may be transferred into a different being in the course of a few weeks' treatment."

Why the Council should accept the work of Dr. Colebrook, which was carried out in a few months, to the opinion of Sir Henry Gauvain and Mr. Duke-Elder, whose clinical experience extends over a number of years, is not clear.

Dealing with the increased hæmobactericidal power after an erythema dose, the Council points out that the effect is transient, that it may be followed by a negative phase, and that the same effect can be obtained from a mustard plaster. On the same page Mr. Duke-Elder's work is referred to, and the conclusion is given: "Some chronic infections of the eye are said to be cleared up better than by any other method." Now, Mr. Duke-Elder's work was carried out with the fractional erythema dose technique, with the avowed object of getting this increased bactericidal power. The hæmobactericidal effect has not been confirmed by workers in England, Denmark, and Italy, and he may have been wrong in attributing the results to this effect. There can be no doubt, however, that his results were due to ultra-violet. He treated some 700 cases and they were not of the type in which "faith-healing and suggestion" could have played a part. The Council cannot have it both ways. Either Mr. Duke-Elder's results are not to be accepted or there is something in ultra-violet treatment. But it is impossible to reject his results, as his work received general commendation and his papers are second to none in the literature on ultra-violet therapy. One wonders whether mustard plasters would have given equally good results.

The Council refers to the "concordant testimony" to the value of artificial ultra-violet rays in chronic tuberculosis but do not accept it, owing to the uncertainty of changes in diet, &c. Cases have been recorded in which there were no such changes. These are ignored. The Council also hints at the possible influences of the visible rays. This is a mere quibble and is purely a technical question of which type of arc is more suitable for treatment.

The Council is on even weaker ground and has less justification for its conclusions on the value of ultra-violet rays in the treatment of local conditions, such as ulcers. After admitting that Mr. Duke-Elder, like some earlier observers, found that direct "local phototherapy" notably hastens the healing of corneal ulcers, it states that there is no equivalent evidence of the successful local treatment of skin ulcers, because Dr. Colebrook failed to heal varicose ulcers. In the first place, the varicose ulcer is not representative of all skin ulcers as there is the obvious factor of the varicose veins. Secondly, Dr. Colebrook's "intensive" inquiry was of little value. It was not an inquiry in the sense that she set out to prove whether ulcers will heal with the technique which proved successful in other hands. She set out to compare the relative merits of Unna's paste and ultra-violet, using a technique of her own. Most of her cases received such small doses that the term ultra-violet treatment cannot be applied to them. As an instance, one case received a total of about half an hour radiation in six weeks, after being ulcerated for years, and yet it was recorded as a failure. This ulcer was so extensive and chronic that she admitted, subsequently, that amputation was advised. The conception of the investigation was such, that the more chronic and consequently the more difficult the ulcer, the less often she saw it (less than once a week). Dr. Colebrook's work was criticised adversely in England and America, and this criticism was never adequately answered. But such is the touching faith of the Council in this intensive inquiry that its conclusions are preferred to the clinical experience of Stebbing, Wilson, Schiller, Bernstein, and others, including Leriche.

The Council goes out of its way to assume that the healing of the ulcers in the B.M.A. series was due to rest and not to the ultra-violet treatment, forgetting that in Dr. Colebrook's series 15 cases were treated in bed and only two healed. Five of the 15 cases received an average of five months' treatment in bed plus ultra-violet first, and bed plus Unna's paste later, and yet none of these five healed. If the assumed rest in the B.M.A. series was responsible for the healing, why did not the rest in Dr. Colebrook's series heal the ulcers? Both the rest and the ultra-violet were strikingly ineffective in the latter.

Mr. Duke-Elder can heal ulcers in the cornea: "In hypopyon ulcers it produces results more satisfactory than can be hoped for by any other method." Dr. J. G. Willmore, who is not a phototherapist, describes dysenteric ulcers which resisted all methods, but healed under the direct application of ultra-violet through the sigmoidoscope. Dr. C. B. Heald employs ultra-violet rays in the treatment of burns. The Finsen Institute treat X ray ulcers with ultra-violet. Various other types of ulcers have been published. The properties of ultra-violet which will heal the above types of ulcers should, on first principles, and in practice do, heal other skin ulcers.

The Council, no doubt, is anxious to establish ultra-violet therapy on a scientific basis, and in this should have the support of every actinotherapeutist. It is, however, to be regretted that the genuine clinical results already obtained should not have received sufficient recognition.

I am, Sir, yours faithfully,

M. WEINBREN.

London, W., March 23rd, 1929.

THE STUDY OF INDUSTRIAL HYGIENE.

DR. CAROZZI'S REPLY TO PROF. GREENWOOD.

To the Editor of THE LANCET.

SIR,—Illness has prevented me from replying sooner to the article by Dr. Greenwood on the study of industrial hygiene, published in your issue of Jan. 26th, but I hope that in spite of the delay which has occurred you will allow me to answer the rather surprising attack which he has thought fit to make on myself, although I have hitherto been a colleague of his on the Subcommittee of Industrial Cancer (Cancer Committee of the League of Nations). Whether it is in accordance with the general canons of professional courtesy to launch a personal and public attack against a colleague without any previous communication is a question on which your readers will be able to form their own opinion.

In the first place, I should like to point out that the pamphlets which the International Labour Office is publishing on industrial health do not purport to describe the conditions in the laundry or any other industry as they actually exist in any particular country. Their object is to summarise the dangers to health which have been found to exist in the various industries wherever they are carried on, in order that those concerned may take the necessary measures to guard against them. In many countries such measures have already been taken to a very large extent in the laundry industry and, as is stated in the pamphlet, "Health conditions in this industry are, in general, satisfactory as compared with other industrial work." I believe this to be generally true so far as Great Britain is concerned, but that does not remove the necessity of pointing out possible dangers, more especially for the guidance of those countries which have reached a less advanced stage in the study of industrial hygiene and the application of modern precautions. Dr. Greenwood's reference, therefore, to "indignant proprietors of laundries" and "intemperate employees who break windows in Whitehall," though no doubt amusing journalism, is quite beside the mark. No laundry proprietor need wax indignant at the contents of my pamphlet and no laundry employee need be led into intemperance, unless the conditions actually prevailing in his own establishment are such as have proved injurious in laundries in the past, but which, I hope and believe, no longer exist in any British laundry. It is not enough, however, to confine attention to cases in which "reasonably good environmental conditions" exist. The chief value of medical research is precisely to bring about the introduction of good conditions by pointing out the dangers to which their absence gives rise.

When, however, Dr. Greenwood suggests that the various diseases which I mention as having been noted in the laundry trade are derived "from uncharted wells of truth known to me alone," he only suggests his own unfamiliarity with the medical literature on the subject. In order to show this, I shall confine myself for the most part to quoting English-speaking authorities with which he might have been expected to be acquainted, and shall leave aside the statements of continental investigators, of whose works he is no doubt ignorant.

Perhaps you would allow me to deal on these lines with the various dangers which have been found in the laundry industry, but which Dr. Greenwood suggests are figments of my imagination. I can best do this by a series of quotations from some of the authorities which I used.

1. *Varicose veins, &c.*—"Much of the work in laundries is carried on in a standing position; hence varicose veins, leg ulcers, and flat-foot are quite common." (Kober and Hayhurst: "Industrial Health," p. 286, Philadelphia, 1924.)

Still more conclusive data on this subject are to be found in the report of an official inquiry entitled: "A Study of Hygienic Conditions in Steam Laundries and their Effect upon the Health of the Workers," New York State Department of Labor, 1924. The data concerning fatigue of the circulatory system have also been published separately in the *Journal of Industrial Hygiene*, November, 1924, p. 270. The inquiry in question covered 110 workers in steam laundries drawn from "some of the best as well as some of the poorer laundries." See also: "The Cost of Clean Clothes in Terms of Health," by Dr. Louis I. Harris, the Director of the Hygiene Section of the Health Department, New York, who found in an inquiry relating to 42 laundries and 3024 persons that 17·5 per cent. suffered from flat-foot. (Ref.: *Bulletin du Service Médical du Travail*, No. 2, 1920, p. 143, Bruxelles.)

2. *Eczema and skin eruptions.*—"Paræsthesia, or a peculiar tingling itching of the fingers, and also an affection of the finger nails, is occasionally observed." (Kober and Hayhurst: Op. cit., p. 287.)

"Some of the bleaching powders used are injurious to the hands of the workers. They are a frequent cause of painful cracking of the skin and of eczema." (Sir Thomas Oliver: "Diseases of Occupation," p. 387, London, 1908.)

3. "*Mycosis* of the external canal, usually *aspergillus nigricans* or *flavescens*, is found in weavers, spinners, wool sorters, and other dust workers handling oily substances as well as in persons working in a moist atmosphere, paper mill tenders, and laundry women for example. . . ." (Kober and Hayhurst: Op. cit., p. 893.)

4. The suggestion that intemperance is liable to prevail among laundry workers is not derived from my fervid imagination but is borne out by a number of authorities, in particular by an article by Miss Lucy A. E. Deane in Sir Thomas Oliver's "Dangerous Trades," pp. 671–72, London, 1902, who says of laundry work: "The work is for the most part exhausting even apart from the conditions, and the pernicious habit of quenching the thirst and stimulating an overtired physical condition with beer is common."

The same phenomenon is referred to in Sir Thomas Oliver's "Diseases of Occupation," p. 389.

Your readers will appreciate from the above quotations that though "the wells of truth" on which I have drawn may be uncharted for Dr. Greenwood, they at least spring from sources which have hitherto been recognised as authoritative in the English-speaking medical world and which will probably remain so in spite of Dr. Greenwood. They could be easily supplemented by references to well-known continental authorities, such as Margoniner, Chajes (1929), Landouzy, and others.

Dr. Greenwood then proceeds to suggest that no marked prevalence of tuberculosis has ever been observed in the laundry trade. The evidence on this subject is so considerable that it is impossible to deal with it at length. I would only refer your readers to Sir Thomas Oliver's "Diseases of Occupation," pp. 390–92, where he states that "laundry workers exhibit a greater liability to pulmonary consumption than women following other employment." He proceeds to quote evidence from an investigation made at the Clapham Infirmary of the Wandsworth Union, and from Prof. Landouzy's researches at the Hôpital Laënnec, Paris, who found that tuberculosis was "present in fully one-third of the 1200 laundresses and female ironers, and in less than one-half of the male laundry workers" treated, and that "out of 238 laundry workers who died in the hospital in five years, 143 died from phthisis." The same phenomenon was found by Dr. Margoniner, in Germany, from whom I derived the statement that the "incipient forms of tuberculosis are not uncommonly diagnosed and treated as anæmia." He states:

"The number of tuberculosis cases is very large, and as an extremely busy practitioner I could establish statistical proof of this if time allowed. The light, or rather the early, stages of lung infection showing dullness, subfebrile forms, are the most common, and are still often overlooked and treated as a species of anæmia." (Margoniner, in "Handbuch d. Arbeiterkrankheiten," Weyl, p. 429.)

Dr. Greenwood then makes play with the statistics quoted in regard to tuberculosis in British infirmaries. The "dubious origin from which these figures were taken" was Sir Thomas Oliver's "Diseases of Occupation," p. 388, and I can only suggest to Dr. Greenwood that he should turn his irony on to Sir Thomas Oliver, who will, no doubt, be quite capable of taking care of himself.

Dr. Greenwood then proceeds to give me a lecture on medico-statistical method, because I stated that in the U.S.A. the "mortality rate for tuberculosis (among laundry workers) is only 16·3 per cent. for both sexes." By wrenching the passage from its context, he attempts to give the impression that I do not understand the American figures. Had he not suppressed the remaining half of the sentence, it would have been obvious that what was meant was not the rate of mortality from tuberculosis per 100 workers, but the mortality from tuberculosis per 100 deaths. Reference to the French text of the article shows at once that I fully understood the significance of the figures. The term, "mortality-rate," tout court, has, it is true, acquired a definite meaning in English, but anybody reading the paragraph of which the offending sentence forms part will have no doubt as to the sense in which the term is here used.

I think I have said enough to show that Dr. Greenwood has allowed his zeal to discredit my work, and apparently that of the International Labour Office, to outrun his knowledge and discretion. I would only like to say once again in conclusion, that the pamphlet in question did not purport to give an account of the conditions at present existing in the British laundry industry as Dr. Greenwood seems to assume, but to summarise the dangers to health to which it has been found particularly liable, as established by the best British, American, and continental authorities on the subject.

As a result of the researches of men like Sir Thomas Oliver and Dr. Collis, great progress has been made in Great Britain during recent years, thanks to the efforts of the Home Office and the employers in the industry, to eliminate the dangers to which attention is called in my pamphlet, and I only hope that its publication may assist to bring about similar progress in other countries.

I am, Sir, yours faithfully,

L. CAROZZI.

International Labour Office, Geneva, March 7th, 1929.

CONGENITAL DISLOCATION OF THE HIP.

To the Editor of THE LANCET.

SIR,—In the leading article on this subject in your issue of March 16th reference is made to the vagaries in the geographical distribution of this congenital defect and to the difference in incidence in the two sexes. Jones and Lovett give 85 per cent. females in an analysis of 3767 cases, and Whitman, in an analysis of 500 cases, found the proportions to be 82·6 females against 17·4 males. As is stated in your article, this sex-incidence is unexplained.

I would tentatively suggest that this high proportion amongst female infants points to the existence of a sex-linked lethal factor associated with maleness, thus causing the intra-uterine death of male embryos in stocks in which this lethal factor is present and transmitted as a Mendelian recessive. Such a supposition might be invoked to explain, in part at any rate, the variations in the geographical distribution. Little and Gibbons have considered the problem of such factors in connexion with sex-linked defects, such as hæmophilia, but it would seem preferable to reserve the term "lethal" to those factors which tend to the production of non-viable offspring. Some of these factors are semi-lethal in that they do not prevent the birth of viable offspring, yet tend to the elimination of the stocks in which they are present. For these factors I suggest the term "phthersigenic," thus making use of the epithet used by Aeschylus to describe the Furies, destructive of the race of the Atreidæ.

ὦμεγαλαύκοι καὶ φθερσιγενεῖς
Κῆρες Ἐρινύες.

[*Seven against Thebes, line 1054.*

I am, Sir, yours faithfully,

Birmingham, March 22nd, 1929. G. A. AUDEN.

POST-DIPHTHERITIC AURICULAR FLUTTER.

To the Editor of THE LANCET.

SIR,—I read with much interest Dr. Patrick O'Donovan's report of his case of post-diphtheritic auricular flutter in your issue of to-day's date. Defects of conductivity are not uncommon in diphtheritic myocarditis, but I have never seen or read of another similar case. The electrocardiograms show extremely well the recovery of the myocardium, not only by the cessation of the flutter, but also by the increased amplitude of the "Q R S" complex and by the reappearance of the "T" wave in the third record (Fig. 3). The preponderance, which by the way is right-sided, tends to persist, as would be expected in a young child. I consider that the improvement in the electrocardiogram is of even greater import as regards the prognosis than is the diminution in the size of the heart.

I am, Sir, yours faithfully,

London, W., March 23rd. JENNER HOSKIN, M.D.

X RAY EXAMINATION AFTER INJURY.

To the Editor of THE LANCET.

SIR,—Last evening I saw a case of sprained ankle. I would not willingly report the case, which was not of an unusual character, were it not for advice which appeared in your issue of March 16th (p. 591)—namely, that "in any case of injury to bones or joints the doctor should *invariably* advise X ray examination" (the italics are mine).

The case was that of a lady, aged about 30, and the history was that of a fall with the left ankle bent beneath the body. First aid was rendered by a labourer, who emerged from a trench in the road, but the lady was able to walk home. She applied a well known liniment and a bandage and then went forth and posted a letter. On returning she rested until my arrival. I found some bruising beneath and in front of the lower end of the left fibula. There was tenderness over the bruised area on pressure, and more still on deep pressure. There was no tenderness over any bone, little swelling, and no limitation of movement which could not be easily overcome. From these and other considerations I formed the opinion that there had been forcible stretching and some rupturing of structures, chiefly ligamentous, on the outer side of the ankle and some effusion of blood, but that there was no injury to bone. Unless the expression "joint" is confined solely to bone, cartilage and synovial membrane, I consider that the joint was injured.

Here, then, was a case in which I had been enjoined, very many times, by the Medical Defence Union, that it was my duty to advise an X ray. Had my own interests only to be considered no difficulty would have arisen. Such apparently is the theory of medical practice which holds sway in the offices of the Union. But, in this case, both the patient and myself understood that I was attending primarily in the interest of the patient, my personal interest being confined to an expectation of legitimate fees. And the patient (this is true of 99 per cent. of my patients) was only willing to incur the expense of an X ray examination if it were my honest opinion that such examination was likely to be of value. I did not think it would be of value, nor am I willing to make X ray treatment a routine, at the bidding of the Union but at the cost of my patients, because there is just a possibility that in the case mentioned there is a concealed spiral fracture of the tibia or something equally unlikely. Indeed, circumstances would not permit me to do so, for I myself own an X ray plant and it would be presumed that my advice was not disinterested.

Nevertheless, if I am mistaken and this case is just the one in a thousand which comes into court, I shall be in an unfortunate position. I shall have acted honestly in my patient's interest, and knowing

that I considered her interest at my own peril. But I shall be confronted by a legal luminary who will be able to prove (*a*) that the Medical Defence Union is officered by persons of distinction in the scientific world or in general practice; (*b*) that these have advised that an X ray is *invariably* necessary in cases of injury to joints, and (*c*) that I have deliberately disregarded their advice. It will be of little use to argue that as a matter of practical politics X ray examination is not always necessary and that there are many cases in which no honest general practitioner would dream of putting his patient to the expense involved. It will be of little use to say that I did my best, a good average best such as is required, and with a single view to my patient's interest. For against all this will stand the damning advice of the Medical Defence Union that X ray examination is *invariably* necessary. Nor can I argue that this advice is an ethical abomination unworthy of a liberal profession, based purely on self-interest and preached from that and no other point of view. For to do so would be to advertise the dishonour of my own brethren. Yet, Sir, they *are* dishonoured by this advice as they must be by any advice which invites them to consider their own interests at the cost, if need be, of those of their patients. And their material interests are not well served by a body which prejudices all future cases by putting such a weapon in the hands of the legal representatives of our opponents.

I may perhaps say in conclusion that I bear no sort of ill-will to any officer of the Medical Defence Union, of which I am a member, but that I consider that the above views cannot be peculiar to myself and are worth considering and answering.

I am, Sir, yours faithfully,

Sevenoaks, Kent, March 21st, 1929. GORDON WARD.

GLASS-WORKERS' CATARACT.

To the Editor of THE LANCET.

SIR,—I am sorry Dr. William Robinson feels aggrieved at the omission of his name from the picturesque notice of my lecture on "Twenty Years' Experience of Compensation for Industrial Maladies." As a matter of fact, I mentioned his paper, having in mind that of Jan. 24th, 1903, in which he was the first, in this country, to describe the posterior cortical cataract of bottle finishers, and I mentioned him by name. But I was not going to deny the credit due to the careful observations, commenced in 1891, of the late Mr. A. Greenwood, the partially blind secretary of the Yorkshire Glass Bottle Makers, on cataract as a cause of superannuation of the members of his society. The subject treated in the lecture was not, who first described the condition, but how did it come to be scheduled as specific to the employment.

I am, Sir, yours faithfully,

London, March 26th, 1929. T. M. LEGGE.

BIOLOGICAL DIAGNOSIS OF PREGNANCY.

To the Editor of THE LANCET.

SIR,—The response to the letter of Prof. R. W. Johnstone concerning the Zondek-Aschheim test for pregnancy, which appeared in your columns on Feb. 9th, has been most encouraging. Already some 90 tests have been carried out and in such cases in which further clinical reports have been received the diagnosis as established by the test has been confirmed. Experience has shown, however, that the working of the pregnancy diagnosis station could be made easier and more fruitful if certain matters of detail were improved. Commonly too much, too little, or too stale urine is sent, and often in packages that are too easily broken in transit. The requirements are 2 oz. of fresh morning urine in a chemically clean bottle enclosed in a package that will withstand the dangers of the journey and accompanied by the following information: Date of last menstrual period; parity; menstrual history; history of any severe medical disturbances. It would also appear necessary to emphasise the fact that the test cannot be made free of cost; mice have to be bought and kept, and it is to cover the cost of these that a charge of 5*s.* for private cases and 1*s.* 6*d.* for institutional cases is necessary. A postal order should therefore be enclosed in the package.

I am, Sir, yours faithfully,

F. A. E. CREW.

Pregnancy Diagnosis Station, The University, King's Buildings, Edinburgh, March 23rd, 1929.

Public Health Services.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED MARCH 16TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week: Small-pox, 286; scarlet fever, 2138; diphtheria, 1112; enteric fever, 40; pneumonia, 4897 (last week 5818); puerperal fever, 45; puerperal pyrexia, 117; cerebro-spinal fever, 16; acute poliomyelitis, 2; encephalitis lethargica, 21; dysentery, 13; ophthalmia neonatorum, 108. No case of cholera, plague, or typhus fever was notified during the week. The notifications of pneumonia are rapidly falling.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on March 19th–20th was as follows: Small-pox, 121 under treatment, 2 under observation; scarlet fever, 1614; diphtheria, 1842; enteric fever, 11; measles, 85; whooping-cough, 1164; puerperal fever, 19 (plus 8 babies); encephalitis lethargica, 79; poliomyelitis, 4; "other diseases," 63. At St. Margaret's Hospital there were 8 babies (plus 3 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there were 2 deaths from small-pox, 4 (0) from enteric fever, 114 (0) from measles, 6 (1) from scarlet fever, 254 (81) from whooping-cough, 41 (5) from diphtheria, 59 (8) from diarrhœa and enteritis under two years, and 1552 (203) from influenza. The figures in parentheses are those for London itself.

Deaths from influenza are thus seen to be on the wane in London as well as in the country as a whole, the actual totals during the previous eight weeks for the 107 great towns being 179, 321, 652, 987, 1243, 1764, 2183, and 2127 respectively, the figures for London during the same weeks being 39, 77, 198, 331, 393, 473, 424, and 312. In the week under review, however, more than 30 deaths were attributed to influenza in the following towns—namely: Birmingham, 173; Sheffield, 89; Bradford, 56; Bristol, 49; Stoke-on-Trent, 47; Manchester, 41; Leeds, 34; Nottingham, 33. The two cases in which small-pox was mentioned as a cause of death occurred in London (Finsbury Met. B.) and Derby C.B.

The number of stillbirths registered during the week was 282 (corresponding to a rate of 39 per 1000 births), including 45 in London.

DONATIONS AND BEQUESTS.—The trustees of the estate of the late Mr. John Rankin, of Liverpool, in accordance with the testator's wishes, have allotted £95,000 to Liverpool Charities, including, besides other large donations, £7000 to the Royal Southern Hospital, Liverpool; £5000 each to the Royal Infirmary, Liverpool; David Lewis Northern Hospital, Liverpool; Incorporated Liverpool School of Tropical Medicine Appeal Fund; Liverpool Hospital for Cancer and Skin Diseases; Liverpool Maternity Hospital Building Fund; and the Liverpool College Building Fund; £3000 each to the Liverpool Queen Victoria District Nursing Association; and the Royal Liverpool Children's Hospital.

Parliamentary Intelligence.

HOUSE OF LORDS.

WEDNESDAY, MARCH 20TH.

LOCAL GOVERNMENT BILL.

THE Earl of ONSLOW (Paymaster-General) formally moved the third reading of the Local Government Bill.

Earl DE LA WARR, in moving the rejection of the Bill, said that the Scottish Bill was more generous in a great many ways. In the present Bill local authorities were to lose their right of discrimination as to whether they should seek to recover expenses for maintenance in one of their institutions. This was justified in Committee by insis ing upon uniformity with the poor-law. When, however, it was pointed out that the words in the Bill were "it shall be the duty of," and that in the poor-law the word was "may" the Government fell back upon that unfailing majority which their lordships had afforded throughout the discussion of the Bill. It was interesting to note in this connexion how far it was possible for two members of the same Cabinet to disagree and for one member of a Cabinet completely to disclaim responsibility for the opinions and actions of another member of that Cabinet. The poor-law would remain after the passage of this Bill very much the same as it was before. The old, the sick, the infirm, and the unemployed were all by this Bill left within the ambit of the poor-law; any real reform of the poor-law must separate these classes.

The LORD CHANCELLOR said the Government believed that in this Bill they had effected improvements in the efficiency of the social services, improvements in the application of public moneys for those services, and that at the same time they had remedied injustices which had too long pressed upon productive industry.

The Bill was read the third time by 70 votes to 11.

Consultation as to the Provision of Hospital Accommodation.

The Earl of ONSLOW then moved an amendment to Clause 13 to meet a point raised by Lord DONOUGHMORE, and to show that the consultation should be continuous.

The Earl of DONOUGHMORE said that the noble lord had met a real anxiety by moving the amendment.

The amendment was agreed to.

The Earl of ONSLOW moved further amendments to ensure that consultation should take place with representatives of the voluntary hospitals both as to the hospital accommodation to be provided, and as to the purposes for which it was to be used. He said that the amendments were introduced by the Government with a view to meeting Lord Dawson as far as possible. They wanted to show that they really wished to meet in every way they possibly could the wishes of noble lords who representated hospitals, and that was the object of this clause. He understood that Lord Dawson would accept it.

Lord DAWSON said he would like to express his appreciation to Lord Onslow for trying to meet the views of those who represented the hospitals as far as possible. He did not pretend that the amendment did all that they asked; but it was impossible to get all that one wanted in an imperfect world, and the new proposal certainly went further than the word "accommodation" alone. Further than that, this clause really did bring people who knew into consultation with those who had to administer. It was a beginning, but he would point out that it did not go quite as far as it would be necessary to go in administrative matters. It had always been a very serious matter that the mass of the medical profession had been divorced from having an effective voice in the health services. That did not matter very much so long as curative medicine was not concerned; but unless some steps were taken to bring the mass of the profession, and those who knew about these things, into responsible contact with those who for the first time were to take such a large part in administering the Bill, he thought the measure was unlikely to have the good effects that were hoped from it. He recognised, however, that the clause gave the right of consultation, and he hoped that out of this poor beginning larger things would grow as years went by.

The amendments were agreed to.

The Bill was passed and returned to the Commons.

HOUSE OF COMMONS.

LOCAL GOVERNMENT BILL: THE LORDS' AMENDMENTS.

On March 22nd the House considered the Lords' amendments to the Local Government Bill.

A New Clause.

Mr. CHAMBERLAIN (Minister of Health), in moving that the House do agree with the new clause providing for consultation as to the provision of hospital accommodation, said that this was a matter of some importance, and was the subject of a considerable amount of discussion in the House of Lords. The purpose of that discussion was to try to ensure that there should be full and ample opportunities for the representatives of voluntary hospitals in any area, including not merely the lay members, but also the medical and surgical staffs, to offer their experience and to put forward their views before the local authority set to work to revise its hospital accommodation. The Government did not desire to put into the Statute more than was necessary, but it became clear in the House of Lords that people of very considerable weight and standing in the voluntary hospital world were not satisfied that, without some statutory provision, there would be that measure of consultation with the representatives of the voluntary hospitals which they felt to be not merely desirable, but vital for the proper development of the hospital services of the country in the future. With the object of the amendment he had been always fully in sympathy. He had a very strong view that the assistance of the voluntary hospitals would be absolutely essential if the municipal hospitals which would be reorganised and conducted by local authorities in future were to be placed on a proper footing. They stood on a very different level from the voluntary hospitals, and it would be a work of time and of care and tact to bring them up, generally speaking, to the same level as that attained by the voluntary hospitals. That could only be done by the exercise of coöperation and goodwill on both sides. He believed that the provision made in the clause, under which there was the duty laid on the local authorities to consult with bodies representative of the voluntary hospitals, would bring about that coöperation and goodwill of which he had spoken.

It would be seen that the body which was to be consulted was such committee or other body as the local authority considered to be representative both of the governing bodies and the medical and surgical staffs of the voluntary hospitals. It would be said, perhaps, that in one area or another there would be no such body. It was quite possible that there was no such body in some areas now, but it was most desirable that there should be such a body, because the voluntary hospitals would never be able to exercise to the full the influence which they should do on the health of the district unless there was coördination among themselves, and unless there was some body which would represent the various voluntary hospitals concerned, and which could speak for the whole of them when dealing with the local authority. Without such a body there would not be the full measure of consultation which was desirable. He regarded the clause, therefore, as one which was likely to have the effect of stimulating the formation of such representative bodies, and from that point of view also he believed it to be a valuable addition to the Bill.

Mr. GREENWOOD said that it was quite clear that if they were to make the best use of the available hospital accommodation there must be consultation between the local authorities and the various voluntary hospitals. But he looked on the new clause with a little suspicion. The Minister of Health seemed to have in hand the organisation of the new voluntary hospitals in the future with a view to preventing the development of the public hospitals. He (Mr. Greenwood) saw no reason why the consultation proposed should not have been confined to the governing committees of the hospitals. Had the Conservative party now turned to Syndicalism? Why should the local authorities have to consult the employees of the voluntary hospitals? The words of the new clause had been put in by the most powerful trade-union in the country. They were initiated and supported by very influential members of the medical trade-union.

Lieut.-Colonel FREMANTLE: What does the hon. gentleman mean by that? Does he mean the British Medical Association?

Mr. GREENWOOD: I mean the organised medical profession of this country.

Lieut.-Colonel FREMANTLE: Which organisation does he mean?

Mr. GREENWOOD: There are more than one, I understand. I see no reason why the hon. gentleman should be ashamed of his trade-union.

Lieut.-Colonel FREMANTLE: I am not ashamed of it, but I want the hon. gentleman to be precise in what he says. (Laughter.)

Mr. GREENWOOD: To please the hon. gentleman I will say at once, the British Medical Association.

Lieut.-Colonel FREMANTLE: May I ask if Lord Dawson has anything to do with the British Medical Association? (Cheers.)

Mr. GREENWOOD: I should think it very unlikely, but no doubt he is a loyal paying member of his trade-union

and is in a position to present its case in the House of Lords. Continuing, Mr. Greenwood asked why it should be made compulsory on the local authorities to consult with the servants of the voluntary hospitals? He was sorry the Minister of Health had lent himself to this new development of Sovietism in a very conservative profession. It looked as if there might be behind this proposal opposition to any development which did not harmonise with their own particular interests.

Sir R. LUCE welcomed the new clause. Some sort of coördination, he said, was essential in the future between the voluntary system and the development of hospitals under the local authorities if a great deal of overlapping was to be prevented. A vast amount of experience had been gained by the voluntary hospitals, not only in the matter of administration, but in matters affecting the coördination of hospital work. There was need for the separation of different kinds of treatment and a vast amount of work was necessary in reorganising and coördinating in order to see that the right kind of work was done in the hospitals throughout the country. That was a matter on which medical advice was necessary. Therefore it was a little unfair to say that the medical profession should not be consulted in this matter. He welcomed the clause very heartily on behalf of those interested in the development of the hospital system and in ensuring that in any future extension of it the wonderful old system of voluntary hospitals should not be elbowed out by processes of nature, but that it should remain the centre round which the new development of hospitals should proceed. They owed to Lord Dawson, who so eloquently and persistently urged the adoption of a clause of this kind, another debt of gratitude in addition to the great debt which the nation owed to him to-day and would never be able to repay him.

Mr. PETHICK-LAWRENCE said that the Minister had given no indication of what the local authority would do in cases where no such committee as was contemplated by the clause existed. There was no obligation on the part of the voluntary hospitals to form such a committee.

Sir A. HOPKINSON said that he had had to deal with just such questions as were raised by the clause, which was an admirable one, and he believed that coördination was absolutely vital in hospital work and development. It was necessary that the medical staff should be consulted, for they were the people who really understood the points in question. In the coördination of hospital work in Manchester he knew that the loyal coöperation of the medical men who had given their lives to this work had been of the utmost value. How could they possibly know what steps ought to be taken, not only in the matter of healing, but of research, unless they consulted the people who had been at work for years in connexion with the various hospitals? There was also the question of the training of medical men and nurses. On that point, after many years' experience, he had come to the conclusion that coöperation between the laymen on the governing bodies, the local authority, and the trained medical men was vitally essential.

Sir H. NIELD said that as one who had been interested in voluntary hospitals for many years he thought that the attitude of the Labour party, who pretended to be the friends of the poor, on this matter was a very ungenerous one. He hoped that they would not hear any more of the ungenerous attacks on the medical profession, who had devoted their lives to the welfare of the public.

Sir H. SLESSER denied that anyone on the Opposition side of the House had attacked the medical profession. They all agreed in paying to the doctors the greatest possible tribute, and the question of the merits or demerits of the doctors, or anybody else, had nothing to do with the matter under discussion. The direction on the clause that the local authorities should consult with certain bodies was only a pious aspiration, for even if these bodies existed and consultations took place nothing was provided as to the consultations being acted upon. The clause could not be interpreted in a court of law, and was meaningless.

Sir KINGSLEY WOOD (Parliamentary Secretary to the Ministry of Health) said that in the House of Lords many most distinguished lawyers and judges who sat on the highest tribunal in the land had devoted considerable time to the discussion and framing of this clause, and he accepted their view that it was likely to have real and practical effect. The object of the clause was to avoid overlapping in the provision of hospital treatment, and he was certain that when the local authorities entered into consultation with the representatives of the voluntary hospitals that that consultation would be of the friendliest nature. He did not believe that these would be empty consultations, but that they would be really in the best interests of the poor and the sick of the country. A very large number of associations representative of the voluntary hospitals already existed in many areas, and where no such associations or committees existed at present the Minister of Health was assured that the voluntary hospitals would see that they were formed. It was obviously to their interests to secure that. The local authorities and the bodies representing the voluntary hospitals could be trusted generally to consult in this matter in a friendly way and to come to a conclusion which would be to the best interests of all concerned.

The new clause was agreed to.

Weekly Contributions to Hospitals.

A further amendment inserted in the House of Lords legalising the practice of associations of wage-earners and persons in receipt of small incomes to contribute weekly sums for the support of poor-law hospitals as well as voluntary hospitals, was agreed to.

Mr. CHAMBERLAIN, in moving that the amendment should be adopted, said that in one case last year nearly £10,000 was paid to the guardians for services rendered by a poor-law hospital.

The remaining amendments were mostly of a drafting character.

WEDNESDAY, MARCH 20TH.

PUBLIC HEALTH IN SCOTLAND.

On the motion for the second reading of the Consolidated Fund (No. 2) Bill a debate took place on Scottish affairs.

Sir ARCHIBALD SINCLAIR raised the question of agricultural research. He said the work which had been pushed forward in that direction during the last few years was resulting in discoveries which would undoubtedly affect the health of future generations. He had in mind particularly the very important research into milk consumption and its effect upon school-children which he hoped would be used by this Government, and future Governments, to bring home to the people the physical advantages of milk consumption and its advantages in conferring upon the youth of the country greater mental energy as had been proved by this research.

Mr. JAMES STEWART urged that something should be done to prevent sewage being poured into the River Clyde by certain local authorities in the Glasgow area. This sewage he said, was endangering the health of the whole community in that region. But the Scottish Board of Health, instead of supporting Glasgow in the matter, had practically said that they could do nothing.

Puerperal Fever.

Turning to the general question of public health the hon. Member said that puerperal fever was still taking as large a toll of life as it did 40 years ago. Apparently science which had reduced the death-rate in other directions had failed in regard to this disease. He would like to know what action the Government were taking in the matter. It might be necessary for the central authority which was finding the money to use some sort of forceful persuasion on the local authorities to induce them to develop their maternity hospital accommodation. It should be possible for every woman at the time of childbirth to have the chance of the best accommodation and treatment. It should not be possible for these women to remain at such a time in the fœtid atmosphere of single-apartment houses in the big cities and in places where the hygienic conditions could not be made suitable. He gathered from the Report of the Scottish Board of Health for 1927 that instead of the cases of pulmonary tuberculosis showing a reduction in that year there was an increase. It was true that the ground which was lost in regard to pulmonary tuberculosis was balanced by ground gained in other respects, but while they had made great progress he would like to know more about what was being done. He believed that they had gone as far in this matter as they were likely to do until the conditions of the people were improved. There was not a medical officer in Scotland who, when lecturing on this subject, did not say something about it being a disease due to poverty, and that its main cause was not merely bad housing, but other bad conditions of almost equal importance.

The Minister's Reply.

Sir J. GILMOUR (Secretary for Scotland) said that he had come to the conclusion that the sewage referred to by Mr. Stewart would be sufficiently aerated and broken up to enable it to be discharged into the Clyde in such a condition that it would not be deleterious or offensive. The matter, however, would be most carefully watched by the Department. He regretted that greater progress had not been made in dealing with the very serious problem of puerperal fever, but they had taken steps to ensure that in future on every death certificate these facts should be notified, and that in itself would be an advance in giving them information which could be tabulated. He would also draw attention to a report by Dr. Kinloch, the new head of the Health Department in Scotland, who spoke with peculiar knowledge on this subject. They desired to draw the attention of the whole medical fraternity to his report which would be made available. He hoped by the steps taken recently in the Scottish Local Government Bill that they would make further progress in regard to the increase of hospital accommodation.

As to the problem of tuberculosis they had made some progress. The rate had fallen from 99 per 100,000 to 97 per 100,000. That, of course, had been mostly in the pulmonary type of tuberculosis. In that alone it had fallen from 71 per 100,000 in 1927 to 68 in 1928. They had the highest number of beds in the hospitals of local authorities that they had ever had—4634—and hospitals had been opened in the Shetlands. Something like £600,000 per annum was being spent by local authorities.

The Bill was read a second time.

Administration of Powerful Drugs.

Sir ROBERT THOMAS asked the Minister of Health whether hospital probationers were entitled to administer powerful drugs, such as digitalin and morphia, in the absence of a qualified medical practitioner; and who was held responsible in the event of the death of a patient as a result of a mistake on the part of a probationer.—Mr. CHAMBERLAIN replied: The answer to the first part of the question is that while the administration of drugs within the scope of the Dangerous Drugs Acts is subject to special restrictions, the responsibility for administration rests with the medical practitioner in charge of the case. I cannot undertake to pronounce the general terms upon the issue raised by the second part of the question, which must turn upon the view taken of particular facts.

Sick Leave among Women Clerical Officers.

Mr. TOWNEND asked the Secretary of State for Foreign Affairs what was the average number of days of sick leave per head during each of the last three years in the case of women clerical workers, writing assistants, and members of the established typing grades, respectively, employed in his department; and what was the average number of days of sick leave per head in the case of each of the grades concerned, taken on account of gastric or nervous trouble respectively.—Sir AUSTEN CHAMBERLAIN replied: The following is the information asked for:—

—	Average number of days' sick leave per head.		
	1926.	1927.	1928.
Women clerical officers ..	7·8	5·8	7·7 (*a*)
Writing assistants	1·5	2·5	1·0
Established typing staff ..	9·0 (*b*)	9·8	7·8 (*c*)

(*a*) Excluding two women who had 86 and 145 days' sick leave respectively.
(*b*) Excluding two women who had 108 and 121 days' sick leave respectively.
(*c*) Excluding one woman who had 204 days' sick leave.

To furnish the information requested in the last paragraph of the question would involve the scrutiny of a large number of medical certificates, and I do not think that the labour involved would be justified.

THURSDAY, MARCH 21ST.

The Lead Paint Regulations.

Mr. VIANT asked the Home Secretary whether he could indicate generally the results of the working of the Lead Paint Act, 1926; and whether he would consider the propriety of ratifying the international convention of 1921 with regard to white lead.—Sir WILLIAM JOYNSON-HICKS replied: Reports recently received indicate that as a result of the coöperation between the inspectors and the industry, substantial progress has been made in compliance with the Act and Regulations, but as the Regulations only came into operation on Oct. 1st, 1927, and have therefore been in force for less than 18 months, it is not possible yet to form any reliable estimate as to their efficiency. The Act was passed on the understanding that before prohibition was resorted to, the effect of regulations should be tried, and I am not therefore prepared to re-open this question at present.

The London Lock Hospital.

Mr. PETHICK-LAWRENCE asked the Minister of Health (1) whether he was aware that there was dissatisfaction at his declared intention to refrain for the present from publishing the report of the committee which inquired into the London Lock Hospital; and whether he had set a time-limit to the board within which the reforms promised by them must be carried out; and (2) whether he would publish the correspondence between himself and the board of the London Lock Hospital, including the letter or memorandum from the board on the strength of which he had decided to refrain for the present from publishing the report of the Committee of Inquiry.—Mr. CHAMBERLAIN replied: I have no evidence of dissatisfaction with the reply which I gave on this matter last week. I have, as I then stated, made myself responsible for ensuring that changes at the hospital are made with sufficient speed; but it is not practicable to impose a time-limit in affairs of this kind. I cannot undertake to publish the correspondence alluded to in the hon. Member's second question.

Small-pox in London.

Mr. DAY asked the Minister of Health the number of small-pox cases notified in the London area during the past three weeks; the districts from which these cases had been reported; and the number of adults amongst such cases.—Mr. CHAMBERLAIN replied: The total number of cases of small-pox notified in the metropolitan boroughs of the Administrative County of London during the three weeks ended March 16th, 1929, was 39—viz.:—

Notified during three weeks ended March 16th.	Cases of small-pox.*	Notified during three weeks ended March 16th.	Cases of small-pox.*
Bethnal Green ..	2	Poplar ..	9
Finsbury ..	4	St. Pancras ..	2
Holborn ..	1	Southwark ..	3
Islington ..	1	Stepney ..	13
Lambeth ..	4		

*Provisional figures.

He understood that 15 of these notifications were in respect of persons of the age of 21 years or over.

Accidents in Factories and Workshops.

Sir WILLIAM EDGE asked the Home Secretary the number of accidents to workpeople in factories and workshops in England and Wales in 1928; the number of fatalities; and whether he was satisfied that adequate progress was being made with the safety-first arrangements.—Sir W. JOYNSON-HICKS replied: The number of accidents, as provisionally ascertained, was 126,366, of which 578 were fatal. As regards the second part of the question, I am glad to say that the action which was taken last autumn, in response to my representations, by a number of important employers' associations, has had good results and that substantial progress is being made in the industries chiefly concerned. A great deal, of course, remains to be done, and there are still many works where no adequate arrangements have yet been set up, but the outlook is distinctly encouraging, and I hope for a much fuller and wider development of this movement in the near future.

Sanitary Arrangements on British Transport.

Mr. THURTLE asked the Secretary of War if he would cause inquiries to be made into the conditions in which troops recently returned to this country from China on board the S.S. *Neuralia*, particularly in regard to the lack of space for sleeping and exercise purposes and the inadequacy of the sanitary arrangements.—Sir L. WORTHINGTON-EVANS replied: The S.S. *Neuralia* is a hired Government transport fitted by the Board of Trade in accordance with the regulations approved for the conveyance of troops by sea. I am informed that the numbers embarked were normal, and that there are no grounds for the suggestion that there was any lack of space for exercise or sleeping or that the sanitary arrangements were inadequate.

MONDAY, MARCH 25TH.

Lepers in India.

Sir ROBERT THOMAS asked the Under Secretary of State for India if he could state approximately the present number of lepers in India; how many treatment centres were now open; to what extent those centres were State supported as regarded initial establishment, maintenance, and payment of their medical staffs; and whether the British Empire Leprosy Relief Association received any financial aid from public funds.—Earl WINTERTON replied: The number of persons in India returned as lepers at the census of 1921, the last official figures available, was 102,513, but it is probable that the number of lepers in India is considerably in excess of that returned. Information is not available as to the number of treatment centres now open in India. With regard to the remainder of the question, as public health is a transferred provincial subject, the matter is one for the local governments and legislative councils. The Indian Council of the British Empire Leprosy Relief Association work in coöperation with the provincial governments and voluntary agencies, and in each province the local governments either support the leper institutions or make a capitation grant to the institutions under the administration of the Mission to Lepers.

Sir R. THOMAS asked if the hon. gentleman was aware that there were more lepers under the British flag than under any other flag?

Earl WINTERTON: I think that is exceedingly probable in view of the fact that one-third of the population of the world is under the British flag.

Mr. DAY asked whether the latest remedy discovered for the cure of leprosy was not greatly alleviating the disease?

Earl WINTERTON: Yes, Sir, I believe that is so. My noble friend has a very distinguished medical adviser at the India Office who is very closely associated with that particular remedy.

Report on Radium Supplies.

Lieut.-Commander KENWORTHY asked the Minister of Health whether he had received the report of the sub-committee of the Committee of Civil Research on radium and radium supplies; and whether it was proposed to publish it in whole or in part.—Sir KINGSLEY WOOD replied: The report has been received and will be published in full very shortly. I may add that a statement of the intentions of the Government in the matter will be made immediately on the reassembling of Parliament.

Cardigan Cure for Cancer.

Viscount SANDON asked the Minister of Health whether his department or the Committee of Medical Research had investigated the Cardigan alleged cure for cancer; and, if so, what was the report thereon.—Sir KINGSLEY WOOD replied: This is one of several alleged cancer cures regarding which my right hon. friend has made some inquiries through the Departmental Committee on Cancer. No information of scientific value was obtained by those inquiries and no report dealing with the cure has been made.

Medical Officers' Accommodation on China Station.

Sir RICHARD LUCE asked the First Lord of the Admiralty if he was aware that in three of the destroyers serving on the China station the medical officers had been obliged to see their patients and keep their medical stores in part of the latrine accommodation of the ships; that the same medical officers unable, owing to lack of accommodation, to obtain cabins, had been refused hard-lying or other allowance in compensation for their discomfort; and if he would inquire into the matter.—Lieut.-Colonel HEADLAM (Parliamentary Secretary to the Admiralty) replied: No, Sir. There is no information at the Admiralty which would support the allegation in the first part of the question. From such reports as are available it is clear that the best arrangements possible have been made to provide emergency accommodation for the additional medical officers whom it was found necessary to appoint to the destroyer flotillas in China. The only application received for the payment of hard-lying money was in 1927. This was refused as the conditions which were represented to exist were not such as to justify the grant of extra pay.

Sir R. LUCE asked if hard-lying money was not instituted for this purpose?

Lieut.-Colonel HEADLAM replied that hard-lying money was not ordinarily payable to officers in destroyers, and the abnormal conditions were not regarded as sufficient to justify a grant of extra pay.

Sir R. LUCE asked if it was not a fact that this extra work had been going on for some considerable time?

Lieut.-Colonel HEADLAM said that he could not answer that question.

Rheumatism among Children.

Brigadier-General WRIGHT asked the Minister of Health if he could state the extra provision of hospital accommodation set aside in the last 12 months for the treatment of acute rheumatism among children; and what was the total number of beds so set aside.—Mr. CHAMBERLAIN replied: No complete particulars are available, but as regards London, the Metropolitan Asylums Board have during 1928 set aside 38 additional beds in their institutions for the treatment of rheumatic affections among children (including rheumatic fever, acute endocarditis, and chorea). The total number of beds provided by the Board for this purpose was 170 at the beginning of the present month, and they are providing 350 additional beds in buildings now in course of construction. Accommodation is also provided for children suffering from rheumatism in other hospitals, institutions, and schools for physically defective children recognised by the Board of Education, but the exact particulars as to the number of beds so provided are not available. I may, however, refer my hon. and gallant friend to the information given on page 65 of the report of the Chief Medical Officer of the Board of Education for the year 1926, and to pages 123 and 124 of the report for the year 1927. Reference may also be made to page 211 of the report of the Chief Medical Officer of my department for the year 1927.

Insured Persons and Rheumatism.

Brigadier-General WRIGHT asked the Minister of Health if he would state exactly what treatment could be obtained under the National Health Insurance Acts by persons suffering from different forms of rheumatism.—Mr. CHAMBERLAIN replied: All insured persons in Great Britain (with the almost negligible exception of voluntary contributors with an income exceeding £250 a year) are entitled to medical benefit. Under this benefit insured persons suffering from any form of rheumatism are entitled to receive from insurance practitioners all such treatment as the practitioners consider to be proper and necessary, except treatment involving the application of special skill and experience of a degree or kind which general practitioners as a class cannot reasonably be expected to possess. Further, if an insured person who is a member of an approved society which has adopted additional benefit No. 10 receives treatment as an in-patient of a hospital, the society may make payment towards the cost of his maintenance and treatment. Finally, as soon as suitable arrangements can be made under additional benefits Nos. 8 and 16, it will be open to societies which adopt these benefits to make payment towards the cost of any special form of treatment of rheumatism (not included under either of the heads referred to above) either by a registered medical practitioner in accordance with an approved special scheme, or through the agency of an approved charitable institution.

Milk-supply Grants.

Sir WILLIAM EDGE asked the Minister of Health the total of the milk-supply grants to local authorities in England in each year since the grants started.—Mr. CHAMBERLAIN replied: The grants for this purpose are included in the total grants paid to local authorities in respect of their maternity and child welfare services, and no separate figures are available showing the actual amount of grants paid for the supply of milk. The closest estimate which can be formed of the total grants paid for this purpose in respect of each of the financial years 1919–20 to 1927–28 is given in the following statement: 1919–20, £80,000; 1920–21, £179,500; 1921–22, £140,500; 1922–23, £103,500; 1923–24, £95,500; 1924–25, £91,000; 1925–26, £93,500; 1926–27, £103,000; 1927–28, £98,000.

Deaths at Oldchurch Hospital, Romford.

Mr. MARCH asked the Minister of Health whether he had had his attention called to a report by the medical superintendent of the Oldchurch Hospital, Romford, that nearly 100 deaths occurred there within three weeks, and that many of the lives might have been saved if it was not for the overcrowding; that the Romford Board of Guardians was waiting for the sanction of the Minister to enlarge the accommodation, but no approval had been received: and if he could state the cause of the delay and what he was doing in the matter.—Mr. CHAMBERLAIN replied: I have seen a report by this officer in which he states that some of these deaths which apparently occurred last month could have been avoided had the guardians taken some notice of his repeated advice with regard to the lack of accommodation. Proposals for the provision of increased accommodation for cases of tuberculosis were submitted by the guardians in August of last year. After consultation with the Essex County Council I came to the conclusion that the provision of additional wards of the ordinary hospital type was necessary, and the guardians themselves adopted this view in a letter addressed to me on Jan. 14th last, when they made proposals for extensions at an estimated cost of £33,000. On Jan. 18th I informed the guardians that I was prepared to consider the provision of additional hospital wards, and on the 22nd inst. a deputation of the guardians was seen by my officers. No detailed proposals had been submitted to me before the interview, but arrangements have now been made for the immediate discussion of the necessary plans between the guardians' advisers and my officers. There has been no delay on my part in dealing with any proposals of the guardians.

Nightwork in Bakeries.

Mr. KELLY asked the Home Secretary whether he was aware that the international convention on prohibition of nightwork in bakeries was still awaiting ratification: and what action he proposed to take.—Sir W. JOYNSON-HICKS replied: The question of ratifying this Convention was fully considered by the Government, and their decision not to ratify was communicated to this House in April, 1926. Briefly, the reasons were that the provisions of the Convention went much beyond the recommendations of the Departmental Committee on the subject, and were too drastic. In particular, objection was taken to the prohibition being applied not only to the operative baker but also to the master-baker himself. Moreover, it appeared from a report by the Royal Commission on Food Prices that the effect of prohibition, if the supply of bread was to be continued as at present, would be to increase the cost of the loaf. These objections still hold good, and I see no grounds for reconsidering the previous decision.

Sick Leave among Women Clerical Officers.

Mr. TOWNEND asked the President of the Board of Trade the average number of days of sick leave per head during each of the last three years in the case of women clerical officers, writing assistants, and members of the established typing grades respectively, employed in his department.—Mr. HERBERT G. WILLIAMS replied: The following table gives the information for which the hon. Member asks in the first part of the question:—

—	Average number of days sick leave per head.		
	1926	1927	1928
Women Clerical Officers	8·0(*a*)	8·3	4·3
Writing Assistants	6·4	7·1	4·5
Established typing grades	7·8	7·0(*b*)	5·2(*c*)

(*a*) Excluding two women who had 155 days sick leave each.
(*b*) Excluding 4 women who had 303, 231, 105, and 101 days sick leave respectively.
(*c*) Excluding 4 women who had 122, 109, 104, and 88 days sick leave respectively.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. G. Nunn is placed on Retd. List with the rank of Surg. Capt.

The following appointments are announced: Surg.-Comdr. A. S. Patterson to *Pembroke*. Surg. Lts. H. E. M. Martin to *Harebell*, and J. G. Holmes to *Malabar*.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lt. D. A. Imrie to be Surg. Lt.-Comdr.
Proby. Surg. Sub-Lt. A. Elliott to be Surg. Sub-Lt.

ROYAL ARMY MEDICAL CORPS.

Maj. J. E. Hoar, Reg. Army Res. of Off., is re-empld. under Art. 507 (*b*), Royal Warrant for Pay and Promotion, 1926.

TERRITORIAL ARMY.

Maj. G. H. R. Gibson to be Lt.-Col. and to comd. the 155th (Lowland) Field Amb.

Maj. J. Ramsay, from T.A. Res. of Off., to be Maj.

Capt. H. H. L. Ellison resigns his commn. and retains his rank.

Lt. J. O. Moffat to be Capt.

ROYAL AIR FORCE.

Group Capt. C. E. C. Stanford is placed on the retd. list.

INDIAN MEDICAL SERVICE.

The Secretary of State for India, in Council, has appointed the undermentioned to permanent commissions in His Majesty's Indian Medical Service: Kenneth Field Alford, Hubert Joseph Curran, Alan Mackenzie Fraser, Brynmor Jones Griffiths, William Parsons Lappin, Eric Alva Ynyr Mackeown, Hugh Thomas McWilliams, George Milne, George Joseph O'Connor, Peter Shannon, David Leo Trant, Harry Silvester Waters, Edward Patrick Walsh, and William James Walsh. Further appointments are about to be made, and young medical men contemplating a medical career in India are referred to the announcement in our advertisement pages.

UNIVERSITY OF ST. ANDREWS.—Arrangements have now been completed for incorporating in the University the Dental School, hitherto carried on in Dundee under the auspices of the directors of the Dundee Dental Hospital and the Council of the Dundee Dental School. Grants have been promised by the Dental Board of the United Kingdom towards the enlargement of the Dental Hospital and the supplementing of its equipment, and towards the remuneration of lecturers in dental subjects. The lectures and part of the practical work will be carried on in the buildings of the Medical School of the University and University College, Dundee, and extended facilities will be provided in the Dental Hospital for clinical instruction in the several branches of the work of dental practitioners.

Medical News.

UNIVERSITY OF LEEDS.—At recent examinations the following candidates were successful:—

FINAL EXAMINATION FOR M.B., CH.B.

Part I.—Bessie Brown, W. H. Craven, H. Denton, C. H. Foster, J. F. Galpine, W. L. Hardman, J. N. Hill, G. M. Holliday, L. Hoyle, Eugenie C. Illingworth, I. J. Keidan, R. G. S. Meadley, C. Poniedel, L. J. Richmond, S. Rosenberg, S. Silman, L. Silverman, W. E. Smart, E. J. Wayne, and J. W. Whitworth.
Part II.—J. Kak, J. Loofe, and G. J. Marks.
Part III.—L. B. Flather, Esther M. Killick (with distinction in Medicine), A. C. Shuttleworth, and Ivy R. Watson.

FINAL EXAMINATION FOR L.D.S.

Part I.—W. Firth and P. W. Thornton.

UNIVERSITY OF MANCHESTER.—At recent examinations the following candidates were successful:—

DIPLOMA IN PUBLIC HEALTH.

Part II.—Andrew Anderson, Helen G. M. Bennett, Mary Evans, J. J. O'Reilly, Mary I. Prentice, Marjorie Reekie, and Kathleen Sheehan.

UNIVERSITY OF LIVERPOOL.—At recent examinations the following candidates were successful:—

FINAL EXAMINATION FOR M.B. AND CH.B.

Parts I. and II.—V. T. Parkinson.
Part II.—Teresa Lightbound.

DIPLOMA IN PUBLIC HEALTH.

Part I.—A. B. Anderson, J. L. Glegg, Kathleen Edgecombe, R. R. Evans, Bridget M. O. Gordon, B. S. Jarvis, I. S. Jones, J. S. Logan, J. Macdonald, J. C. MacFarland, R. L. McMorris, E. Miles, R. J. Ormsby, D. E. P. Pritchard, F. L. Smith, and F. C. Speechly.

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.

Parts I. and II.—W. H. Milligan, J. E. C. Walker, P. H. Whitaker, and J. Wilson.

DIPLOMA IN TROPICAL MEDICINE.

K. B. Chakravarti, J. Crawford, W. C. Dale, J. R. Dogra, G. D. Drury, T. S. Gill, Margaret Al. Herbertson, J. A. L. Innes, J. A. McGregor, W. B. McQueen, B. K. Majumdar, I. C. Middleton, J. T. F. Pearse, C. Ramdeholl, Elizabeth J. Robinson, P. B. Robinson, A. Shafi, T. Verghese, and S. P. Wilson.

DIPLOMA IN TROPICAL HYGIENE.

S. W. H. Askari, A. Halawani, I. S. Hilmy, H. S. Lawrence, and H. M. Setna.

UNIVERSITY OF DUBLIN: *Trinity College.*—At recent examinations the following candidates were successful:—

FINAL EXAMINATION FOR M.B., B.CH., AND B.A.O.

Part I. Therapeutics, Pathology, &c.—*S. Moore, *Samuel Levy, William Caldwell, F. M. Lyons, and (in completion) C. H. Hutchinson and A. A. Lisney.
Part II. Medicine.—A. F. Kennedy, L. B. Harris, F. R. Falkiner, T. B. McMahon, John Beggs, P. A. Thornton, E. V. Hicks, Nathan Shapira, E. B. Solomons, G. B. Thrift, R. M. Wilson, M. E. Kirwan, N. S. Klass, M. H. Fridjhon, J. A. Dowds, Cecil King, and N. H. Lindsay.
Surgery.—J. E. C. Cherry, Nathaniel Burstein, P. A. Thornton, Anna M. E. McCabe, Hyman Dundon, W. B. Hamilton, W. A. Y. Knight, and Josephine M. Enright.
Midwifery.—*J. N. U. Russell, *E. F. St. J. Lyburn, H. T. Fleming, Patrick O'Shea, R. E. Hemphill, Lilla M. Spiller, E. F. S. Morrison, G. R. Beare, Arnold Rose, Kathleen A. Wilson, Samuel Beggs, Dora G. Bradley, R. T. O'Shea, R. P. McGarrigle, Frances E. Wilson, Nathan Shapira, John Willoughby, and E. J. M. Bam.
* Passed on high marks.

F. J. P. McCarthy has passed the Final Examination in dental surgery and associated subjects for the B. Dent. Sc., and I. S. Marwah the examination for the Diploma in Gynæcology and Obstetrics.

Lord Dawson has been appointed a member of the General Council of King Edward's Hospital Fund for London.

NAVAL MEDICAL COMPASSIONATE FUND.—A meeting of the subscribers of this Fund will be held at 11.30 A.M. on April 25th at the Medical Department of the Navy, Queen Anne's Chambers, Tothill-street, Westminster, S.W.1, to elect six directors of the Fund.

THE Standing Committee of the Universities Bureau of the British Empire have recorded their sorrow for the death of Dr. Alex Hill, secretary of the Bureau, referring to the "attractive personal qualities of modesty, diligence, unselfishness, and geniality of temper" which "endeared him to his colleagues and ensured the smooth and happy working of the machinery he did much to create and develop."

Sir Robert Armstrong-Jones has been appointed Sheriff for Carnarvonshire.

UNIVERSITY OF OXFORD.—Dr. O. A. Beadle has been elected to a Radcliffe Travelling Fellowship and Dr. S. C. Dyke has been awarded the Radcliffe Prize for the furtherance of medical science.

UNIVERSITY OF LONDON.—At a meeting of the Senate on March 20th it was resolved to institute an academic diploma in Public Health.

Mr. Harold Raistrick, D.Sc., was appointed as from August 1st, 1929, to the University Chair of Biochemistry tenable at the London School of Hygiene and Tropical Medicine, where he will also hold the position of Director of the Division of Biochemistry and Chemistry as applied to Hygiene.

From 1915–20 Dr. Raistrick was engaged on research work on the biochemistry of micro-organisms for the Medical Research Committee in Sir Frederick Hopkins's Laboratory at Cambridge. Since 1921 he has been on the research staff of Messrs. Nobel's Explosives Company, Ayrshire, where he has organised and equipped a new biochemical research department.

The degree of D.Sc. in Anatomy was conferred on Mr. W. B. Crow for a thesis entitled Contributions to the Principles of Morphology.

LONDON HOSPITAL MEDICAL COLLEGE. — The Hutchinson Triennial Prize, of the value of £60, will next be awarded in 1932, for a dissertation on the Remote Consequences of Fracture of the Spinal Column. A candidate is eligible to compete until ten years after registration as a student of the hospital.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—The courses to take place after Easter are: A fortnight's course for practitioners at the London Temperance Hospital, in medicine, surgery, and the specialties, from 4 to 5.30 P.M. daily, beginning on April 8th; a series of eight lecture-demonstrations at the London School of Tropical Medicine on Tuesdays and Fridays from April 9th; a course of four lecture-demonstrations on light and heat therapy at the Royal Free Hospital on Wednesdays from April 10th; a three weeks' course in medicine, surgery, and gynæcology at the Royal Waterloo Hospital from April 15th; and a course in neurology at the West End Hospital for Nervous Diseases. This last course will be from April 15th to May 11th, and will consist of lecture-demonstrations, at 5 P.M. (minimum entry ten). Detailed syllabuses may be had from the Secretary of the Fellowship at 1, Wimpole-street, London, W. 1. and also information on post-graduate work in London at the general and special hospitals affiliated to the Fellowship.

The Fellowship proposes to start a course for the July examination for Membership of the Royal College of Physicians of London. Sixteen lectures will be given. Further details are obtainable on application.

UNIVERSITY COLLEGE HOSPITAL.—At the annual meeting of the corporation of this hospital last week, at which Prince George was elected President, it was stated that the reconstruction of the main buildings has been completed and that the full complement of 529 beds is now available. The new preliminary training school for nurses, to which the Rockefeller Foundation has given £31,000, is being erected and will be completed within the next 12 months. The number of in-patients increased from 6580 to 7753, and of out-patients from 247,786 to 258,142. The hospital is seriously handicapped by the insufficiency of its supply of radium.

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the Case Committee 47 applications were considered and 44 grants were voted, amounting to over £979. The following is a summary of three cases of widows who have been helped:—

Widow, aged 52, of M.R.C.S. who died in February. Has been left with a capital of £300; her income can only be £15 a year. A few friends have clubbed together and have promised to give £60 yearly. The Fund voted £36.

Widow, aged 41, of M.R.C.S. who died at the age of 56 in February. It is hoped that the practice will be sold for £1750, the interest on which will be the widow's only income. There is a boy of 9 to educate. The Fund voted a maintenance grant of £26 and efforts will be made to find salaried employment for the widow and help will be given when necessary for the education of the boy.

Widow, aged 65, of L.R.C.P. & S. Was left destitute on the death of her husband. She has supported herself as companion to a lady, but has broken down in health. She has had to undergo an operation and is now a semi-invalid. Her income is £77 per annum. Fund voted £26.

Subscriptions and donations are urgently needed and should be sent to the hon. treasurer of the Fund, at 11, Chandos-street, London, W.1.

DUDLEY GUEST HOSPITAL.—In consequence of heavy pressure upon the beds and a long waiting-list, a number of new wards are to be added at a cost of £50,000.

LIVERPOOL ROYAL INFIRMARY.—In consequence of the success of the penny-in-the-pound scheme a further section of the new nurses' home is to be built. The old home will be used to increase the hospital accommodation.

NOTTINGHAM GENERAL HOSPITAL.—Last year the in-patients numbered 6395, who, at £3 0*s.* 10*d.* per week, cost an average of £7 19*s.* The average per occupied bed for the year was £158 3*s.* 10*d.*, an increase of £6 8*s.* 7*d.* over the previous year. An additional storey is to be added to form a children's ward.

BIRMINGHAM GENERAL HOSPITAL.—Huts containing 60 beds and a new casualty department are to be erected to enable casualties and in- and out-patients to be dealt with more adequately. A diabetic clinic has been established under Dr. A. P. Thomson, and an asthma clinic under Prof. W. H. Wynn is being worked with a committee formed to promote investigation into this disease.

THE MANCHESTER HOSPITALS.—Last year out-patient attendances at the Manchester and Salford Hospital for Skin Diseases exceeded 82,000, an increase of nearly 7000. The increase was largely due to attendances of patients for artificial sunlight treatment, which numbered 16,000. Nearly 30 per cent. of the total income was derived from voluntary contributions by patients.—Nearly 20,000 cases were treated in 1928 at St. Mary's Hospital for Women and Children. During the year 49 medical men and 48 nurses received special instruction.

QUIET SLEEP IN HOSPITALS.—The Leicester and County Saturday Hospital Society last year raised £45,521, an increase, notwithstanding local trade depression, of £1440. Reporting on the Desford Hall Convalescent Home, Dr. Gordon Kelly told the annual meeting that he had been so much impressed by the delight of the patients in uninterrupted sleep that he was suggesting to the Board of Leicester Royal Infirmary the desirability of getting the street adjoining the infirmary closed to vehicular traffic after 9 P.M.

Medical Diary.

SOCIETIES.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos-street, Cavendish-square, W.

FRIDAY, April 5th.—8.30 P.M., General Meeting. Papers will be read by Dr. H. M. Hanschell and Mr. A. O. Ross on the Problem of the Treatment of Venereal Disease in the Mercantile Marine. A discussion will follow.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, April 4th.—4 P.M., Mr. Browne: Talipes.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, April 5th.—4 P.M. Mr. Watkyn-Thomas: The Dying Labyrinth.

Appointments.

CAMPBELL, J., M.B., Ch.B. Aberd., has been appointed Medical Referee for Shetland District; and JONES, A. E., M.B., Ch.B. Glasg., Medical Referee for Kilmarnock District and the Isle of Arran, under the Workmen's Compensation Act.

FAIRLEY, N. H., M.D. Lond., F.R.C.P. Lond., Assistant Physician to the Hospital for Tropical Diseases and Director of the Clinical Laboratory at the Seamen's Hospital.

STEPHENS, J. W. W., M.B., B.Chir. Camb., D.P.H., Honorary Consulting Physician to the Royal Infirmary, Liverpool.

St. John's Hospital for Diseases of the Skin: CORSI, H., M.B., B.Chir. Camb., F.R.C.S. Eng., and TATE, B. C., M.B., B.Chir. Camb., M.R.C.P. Lond., Medical Registrars.

Vacancies.

For further information refer to the advertisement columns.

Altrincham General Hospital.—H.S. At rate of £105.

Ascot Heatherwood Hospital.—Res. Asst. M.O. £300.

Bangor, Carnarvonshire and Anglesey Infirmary.—H.S. £200.

Bedford County Hospital.—H.S. At rate of £175.

Beit Memorial Fellowships for Medical Research.—Jun. Fellows. £400.

Belgrave Hospital for Children, 1, Clapham-road, S.W.—H.S. Also Asst. H.P. Each at rate of £100.

Bexhill, Borough of.—M.O.H. £800.
Bolingbroke Hospital, Wandsworth Common, S.W.—H.P. At rate of £120.
Bombay, Goculdas Tejpal Hospital.—Hon. Surgeon. Rs.150 per mensem.

Tynemouth Union, Poor-law Institution, Preston-road, North Shields.—Asst. M.O. At rate of £300.
West End Hospital for Nervous Diseases, Welbeck-street, W.—Two Hon. Anæsthetists.
Western Skin Hospital, 44, Hampstead-road, N.W.—Hon. Asst. Dermatologist.
Wolverhampton, Royal Hospital.—Res. M.O. At rate of £150.
Worcester General Infirmary.—Jun. Res. M.O. £120.
York, Maternity Hospital and Sanatorium.—Res. M.O. £350.

Births, Marriages, and Deaths.

BIRTHS.

GERVIS.—On March 21st, at Welbeck-street, the wife of Harvey Gervis, F.R.C.S., of a son.
THOMPSON.—On March 17th, at Scarborough, the wife of Guy L. Thompson, F.R.C.S., of a daughter.

MARRIAGES.

KELLY—AUSTIN.—On March 16th, at Holy Family Church, Leeds, John Anthony Kelly, M.B., B.Ch., to Pauline Winifred, daughter of the late Mr. and Mrs. T. Austin, of Leeds.

DEATHS.

BYHAM.—On March 19th, suddenly, at Woodlands, Sunbury-on-Thames, William Louis Byham, L.R.C.P., L.R.C.S., a few days before his 67th birthday.
CUMBERBATCH.—On March 23rd, at Great Sarratt Hall, near Rickmansworth, from pneumonia, Alphonso Elkin Cumberbatch, M.B., F.R.C.S., in his 82nd year.
HAWTON.—On March 19th, James William Hambley Hawton, Fleet Surgeon, R.N. (retired), aged 78.
MCDOUGALL.—On March 18th, in London, of pneumonia, Hugh McDougall, M.D., late of Amoy, China, aged 74.
MAY.—On March 19th, at Pilton House, Pinhoe Devon, Henry Ernest May, M.A., M.B., B.Chir. Camb.
WHITTALL.—On March 18th, at Liverpool, Cyril Hubert Whittall, M.B., Ch.B., aged 39.
WOOLHOUSE.—On March 19th, at Carsick, Sheffield, of influenza, Frederick Woolhouse, M.R.C.S., aged 85.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE HEALTH AND CLEANLINESS COUNCIL.

ADDRESS BY COLONEL FREMANTLE, M.D., M.P.

THE third annual general meeting of the Health and Cleanliness Council was held on March 20th when a large number of its members, including representatives of the Society of Medical Officers of Health, of health and education committees of county, borough, and urban district councils, and of welfare centres and allied movements assembled at the Hotel Cecil for lunch, the President of the Council, Dr. G. F. Buchan, occupying the chair.

Following the toast of the King, Lieut.-Colonel F. E. Fremantle, M.P., proposed the prosperity of the Health and Cleanliness Council in a speech, eloquently describing what such a Council had done and might do. He said that he felt himself among friends who had journeyed along parallel roads with himself, engaged with the same spirit in the common task of propagating health and cleanliness. He commended in high terms the literary propaganda of the Council, which was now distributed all over the country, and specially commended for study the lecture which Prof. Bostock Hill had delivered before the Royal Sanitary Institute in January last, in which there was surveyed the whole of health progress, bringing to notice the personal hygiene inculcated by Moses, the water-supply and sewage disposal of Rome, the epidemiological lessons to be derived from London during the great plague and fire, the message from Erasmus to Cardinal Wolsey about the sweating sickness, and the work of Dr. Thomas Trotter, physician to the Navy at the end of the eighteenth century. These things, together with the more modern story, showed how, and how unconsciously the existing régime of a definite organised and recognised prevention of disease and promotion of health had come about. But, said Colonel Fremantle, Prof. Bostock Hill had ended by emphasising the necessity of cleanliness of mind and the cultivation of the health spirit, and that line, the speaker thought, was the essential one, and it was to inculcate the value of a command of the body by the mind and spirit which was the true message of the Health and Cleanliness Council, as it was also the thing which distinguished the sanitation of the future from that of the nineteenth century, and which really went to the root of the health movement of to-day. Quoting from the psychologist, William James, in an address to students on Some of Life's Ideals, Colonel Fremantle said that the hell of the theologian was no worse than the hell we made for ourselves in this world by habitually training our characters in the wrong way, and the great need was to teach a healthy habit of thinking, especially to children—the adult being perhaps past praying for. The chief lessons of the child's life did not depend on his muscle and nerve-fibres but upon the spirit within him, and it was taking this truth into account that made him happy to commend the activities of the Health and Cleanliness Council. He did not belittle the necessity of getting an ample supply of good houses at a favourable rental, but he did say that that was not the essential thing, for people who could not get such houses could by personal volition go much further than they did towards leading healthy lives and bringing up their children to be healthy. But the housing movement should be advanced on proper lines, and the garden city project emphasised the possibilities. Sanitation was good and necessary, and was the work of the health and educational authorities, but the work of the Health and Cleanliness Council was to promote the health spirit and not merely to obviate discomforts of the body. The ideal should be an active life, a life of health which was so great that it could afford within its own lines to break rules of health. But it was necessary to keep a sense of proportion and to live life as a whole in the spirit of health. In conclusion, he advocated the carrying out of the work of the Council in accordance with the true ideals of art and religion at their best, and he said that the services of the artist, especially of the caricaturist, should be employed to present the main principles of the movement in order to bring home to the public a general picture of the healthy mind, body, and spirit which formed the true ideal of the healthy life.

In his reply for the Council, the President, Dr. G. F. Buchan, M.O.H. for Willesden, outlined the work of the Council for the past year. The policy of the Council was to work in coöperation with health societies, local authorities, and organisations, and during 1928 they had assisted at 156 Health Weeks of local authorities, and made awards in respect of as many as 1750 essays by school-children sent in in competition. During the same year no less than 5,000,000 copies of the Council's publications were sent to 2300 districts in England and Wales, while their book,

"Health and Cleanliness," was used as a text-book by teachers in many schools. He referred to the publicity which was obtained by the representation of the Council in the Lord Mayor's Show through the kind offices of Colonel Blackham, and contrasted the advantages which prevailed in America with those which obtained in this country for the better promotion of health, especially through the provision of bathrooms. Representations had been made to the Council, he said, as to the condition of railway carriages, but he pointed out that it was not the policy of the Society to interfere with private firms or corporate undertakings, but rather to inculcate in the public generally habits of cleanliness so that they will naturally demand cleanliness in others. Finally, he justified the work of the Council by the general statement that the public standards of cleanliness ought to be raised, and people brought to recognise that cleanliness had a wide significance which was biological and not only æsthetic.

OPHTHALMIC HOSPITAL OF THE ORDER OF ST. JOHN.

ACCORDING to the annual report for 1928 the number of patients examined at this hospital at Jerusalem during the year was 20,390. Of these, 2254, or 11 per cent., were blind in one or both eyes, the great majority as the result of acute epidemics of conjunctivitis causing corneal ulceration and ending in either total corneal opacity, shrunken globes, or secondary glaucoma. The proportion of blind cases has considerably decreased since the years succeeding the war, but the percentage for 1928 shows a slight increase on that for 1927 owing to the increasing severity of the epidemics of contagious conjunctivitis since 1926, coinciding with the shortage of rains in the winters of these years. Most cases are complicated by trachoma, the incidence of which was 91·3 per cent. as against 78 per cent. in 1926, an increase attributed to the greater proportion of Moslems attending, and the decreased proportion of Jews, the former being the most infected. The work of the hospital is supplemented by that of clinics at six local centres. The operative work both at the main hospital and at the clinics is concerned with trichiasis, a sequela of trachoma, in just over half the cases, and even so the report says that the hospital is still unable to cope with the stream of trichiasis cases that come for treatment.

THE TUBERCLE BACILLUS.

Henry C. Sweany has contributed to the *American Review of Tuberculosis* (1928, xviii., 630) an important and finely illustrated paper on variations occurring in the tubercle bacillus. His procedure has been to watch for unusual forms of the tubercle bacillus—e.g., those showing granules—in culture and in the cadaver, to pass such variants through a series of guinea-pigs and to study any changes in cultural, staining, and pathological characteristics. He has found it possible to restore degenerate forms of tubercle bacilli to forms revealing the characters of the typical human strain. Ordinary micro-organisms unrelated to tubercle will not regenerate in this way. The variant forms should be distinguished from the mutant forms whose degeneracy has become fixed and irreversible.

In the December issue of the same journal Morton C. Kahn and John C. Torrey present a preliminary report on their observations of the developmental cycle occurring in isolated tubercle bacilli growing in a suitable nutrient medium under the microscope. As the result of cleavage in the bacillus acid-fast coccoid bodies, and at times non-acid-fast globoid forms were developed. Further division of the coccoid forms produced diplococcoid types. After further subdivision numerous minute coccoid non-acid-fast forms were seen possibly identical with those described by Much. At a later stage the cocci gave place to dust-like particles, possibly fine enough to pass through a filter. Eventually extremely delicate rods made their appearance from the growth of which adult acid-fast rods were produced. Whether similar developmental cycles occur in the animal body has yet to be determined.

LABORATORY ASSISTANTS' ASSOCIATION.

THE Pathological and Bacteriological Laboratory Assistants' Association continues its successful and useful career. From the last annual report we learn that there are now 534 members organised in eight branches in England, Wales, and Scotland (Ireland seems to be missing), with Overseas' members in various parts of the Empire. The association is an old-fashioned trades-union; its energies are mostly devoted to coöperative education, and as the result of annual examinations held in conjunction with the Pathological Society of Great Britain and Ireland, certificates of proficiency in practical laboratory work are given to the successful candidates. The syllabus for these examinations has recently been revised and candidates can now take either pathology or bacteriology or pathological chemistry as their major subject, with a variety of additional special branches. At the last examination 18 out of 46 candidates were successful, a proportion which speaks well for the stringency of the tests. The council of the association no doubt realises the importance of keeping up the standard, and we believe that the possession of one of their certificates is a real guarantee of proficiency. So long as they may so be trusted, all workers in medical science laboratories will have reason to be grateful to the association for the good work they are doing. Their *Laboratory Journal* contains many useful practical notes and articles. The president of the association is Prof. W. W. C. Topley, and the secretary Mr. H. Gooding, 10, Holbeck-grove, Victoria Park, Manchester.

PLAGUE CAUSED BY AN INFECTION OF THE MIND.

A CORRESPONDENT writes: The following thanksgiving ordered to be used in Elizabethan times may not be generally known and in its quaint wording is worth republishing:—

THANKSGEUING TO GOD FOR WITHDRAUING AND CEASING THE PLAGE. 1563.

WEE yield the hartie thankes, O most mercifull father, that it hathe pleased the in thy wrayth to remember thy mercie, and partlie to mittigate thy severe rodde of this terrible plage, wherwith thowe hast hitherto most iustly scourged vs for our wickednes, and moste mercifully revoked vs from the same. Callinge vs (who in healthe and prosperitie had cleane forgotten bothe the and ourselves) by sicknesse and adversitie to the remembrance bothe of thy iustice and iudgmente and of our owne miserable fraylenes and mortalytie: and nowe leaste wee by the heavines of thyne indignation, shulde have utterly despeyred, comfortinge vs aigayne by the manifeste declaration of thy fatherly inclynation to all compassion and clemencie. Wee beseche the to perfecte the worke of thy mercie gratiously begone in vs: and forasmoche as trewe healthe is, to be sownde and troow in that parte, which in vs is moste excellent, and like to thy godheade; we praye the throughly to cure and heale the woundes and diseases of our sowles, grevously wounded and poysoned, by the deyly assaults and infections of ye olde serpente Saitan, with the deadly plages of synne and wickednes: By the which inwarde infection of our myndes these outwarde diseases of our bodyes have by ye order of thy justice, O Lord, issued and followed, that wee by thy fatherly goodnes and benefytt, obteyninge perfecte health bothe of our myndes and bodies, maye render vnto the therefore contynewall and moste hartie thankes, and that, by flyenge from sinne, wee maye avoyde thyne anger and plages, and ever hereafter, in innocencie and godlynesse of lyffe studienge to serve and please the, maye bothe by our wordes and works allwayes glorifye thy holly name. Which wee besech the to graunt vs, O father of mercies and goode of all consolation, for thy deare sonne, our only saviour and mediator, Jesus Christs sake. Amen.

THE STABILITY OF BLEACHING POWDER.

IN considering the chlorine treatment of drinking-water in our columns a few weeks ago (THE LANCET, Feb. 16th, p. 352) it was remarked that bleaching powder, however cheap and accessible, has proved too erratic for general use as a water disinfectant. We now learn from the technical department of Imperial Chemical Industries Limited that this reproach is to be removed. It is admitted that bleaching powder exposed to a moist atmosphere will absorb moisture and decompose, and that until quite recently it was not prepared in a form sufficiently stable for it to be reliable after any great length of time, particularly when exposed to hot climates. During the last few years, however, great strides have been made in improving the stability of this commodity, and a special grade of Tropical Bleaching Powder is being produced which is remarkably stable even in hot climates. It is a fine white powder containing 25 per cent. of available chlorine, which survives the test of heating in an oven at 140° F. for 28 days without losing as much as 2 per cent. of available chlorine, a test regarded as severe as a year's storage in tropical climates. Samples returned after having been stored in the tropics for two years have shown a decrease of available chlorine only from 25·2 to 23·9 per cent. The test of exposure to a humid atmosphere is not regarded as relevant to this preparation which is supplied in air-tight packages. In this condition, its stability is said to be as satisfactory as that described for succinchlorimide.

LONDON FEVER HOSPITAL.—The number of fever patients treated last year increased by 400 over that of the previous year. Scarlet fever, diphtheria, and measles were the principal causes of the increase. Dr. C. R. Box, the visiting physician, states that the diphtheria cases were not only more numerous, but more severe. Of the 1276 patients treated, 1076 were fever cases, and 200 cases of pulmonary or other forms of tuberculosis. All new nurses who consent are tested for susceptibility to diphtheria and scarlet fever, and if found susceptible are immunised.

MEDICAL EDUCATION IN THE UNITED STATES AND CANADA.

MEDICINE, a science and an art, has no territorial boundaries. However varying in details and in general sequelæ, and however those sequelæ may be influenced according to environment, climate, and circumstances, disease will have general manifestations; there is always something common about pathology making of disease a great international concern and a link between all the peoples of the world. It follows that as far as disease, its manifestations and its expressions, are common, there should be some common form recognised by modern knowledge to be the best by which to train up those who have to combat disease—some form which, while it is applicable, so far as it goes, to the needs of to-day, should be a preparation for the developments of the future.

An English-speaking Union.

The education of medical students on some international pattern would mean a reciprocity in medicine which none of us will live to see, and for which civilisation is not prepared; but, nevertheless, such an event is nearer than would have been thought possible when intercommunication between nations was more limited, and while our conceptions of pathology were less broad. Already the knowledge that British medical men are trained from the start in a form which is comparable to that which prevails in the United States and Canada shows that a practical reciprocity between the medicine of the English-speaking peoples exists, and may be making ready the path for a larger fusion. Hence the pattern of the medical education prevailing on the other side of the Atlantic is important to us all, both for what it is and what it may later imply. Further, fullness of understanding between the English-speaking peoples in all departments of life must make for the happiness of a world that is so permeated with their energies. The informal report which follows is the outcome of a sojourn in the United States and Canada, having these views as its inspiration. An endeavour is made to set out in a succinct shape the educational curricula, as pursued in a representative group of American and Canadian medical centres, in order to see how far the admitted similarity between them and our British curricula is fundamental and what the divergencies may be. The medical centres selected for personal visit number fourteen—twelve in the United States, and two in Canada—and, while it is an undoubted defect in the undertaking that the personal inspection had to be thus limited, the representative character of the Universities, whose medical Faculties are thus brought under notice, will not be disputed.

Centres Visited.

In the United States the representative of THE LANCET visited the Universities of Harvard, Cornell, Columbia, New York, Yale, and Pennsylvania, the Jefferson College, Johns Hopkins and North-Western Universities, and the Universities of Chicago, Illinois, and Ann Arbor; in Canada, McGill University, Montreal, and the University of Toronto were visited. At each University he received the most ample assistance and the readiest help, and our gratitude is extended to all those connected with the different centres of medical education—a very large number—who made it possible for this report to be written.

Medical men in the United States, Canada, and Great Britain are familiar through an English-written medical press, and through many opportunities of personal intercourse, with the leading developments of medical theory and technique in each country; thus they can institute comparisons, giving support to and taking from each other's performances; so what may be called the end-products of our systems of education are known to us. But those systems themselves come under no similar process of inspection, and no such common familiarity with their details exists. Yet, every whit as much as in our pathology, it is of high importance that we should each know what the other is doing; and in the field of undergraduate medical education we can learn much from a pooling of mutual experiences. Just as the manifestations of disease are common so the great objectives of early medical training are common, whatever particular country is in question—if, of course, its standard of civilisation is sufficiently high. All know it to be desirable to educate those who join the ranks of medicine so that the new men shall be able to carry on their work in two main directions—directions which are but two sides of the same road. Those who would join our ranks must be turned out from their medical schools fit to conduct the service of healing for the public good, and they must also have such a conception of the science and art of medicine that they will be able to appreciate and assimilate the meaning of new developments, and, if opportunity arises, to assist in these developments by personal contributions.

Variations in the Curriculum.

These notes on undergraduate medical education form a matter of fact attempt to place before the readers of THE LANCET a précis of medical education as it is conducted at the selected centres, the shape in which the information is supplied being that of the usual educational supplements of THE LANCET dealing with the British medical schools. The history of a school is often pertinent to its development, and a few words are generally included upon the subject; the various curricula are set out in some detail, and the material facilities offered to the students are described, in some cases more fully than in others, while notes are added upon the institutions, small and great—often palatial—at which the clinical instruction is given. How much the whole educational course is the same at each of these centres is revealed by repetitions, and the similarity of these courses to our own statutory pattern, as regulated by the General Medical Council, emerges and reveals the gratifying fact that, in seeking models, neither the United States nor Canada has had any hesitation in looking to Great Britain. At the same time profound differences of ideal and action are evident. The notes upon the fourteen centres are followed by reflections upon these differences, for the comprehension of where the systems of education vary will suggest the places where progress may be made by selection.

MEDICAL EDUCATION IN THE UNITED STATES.

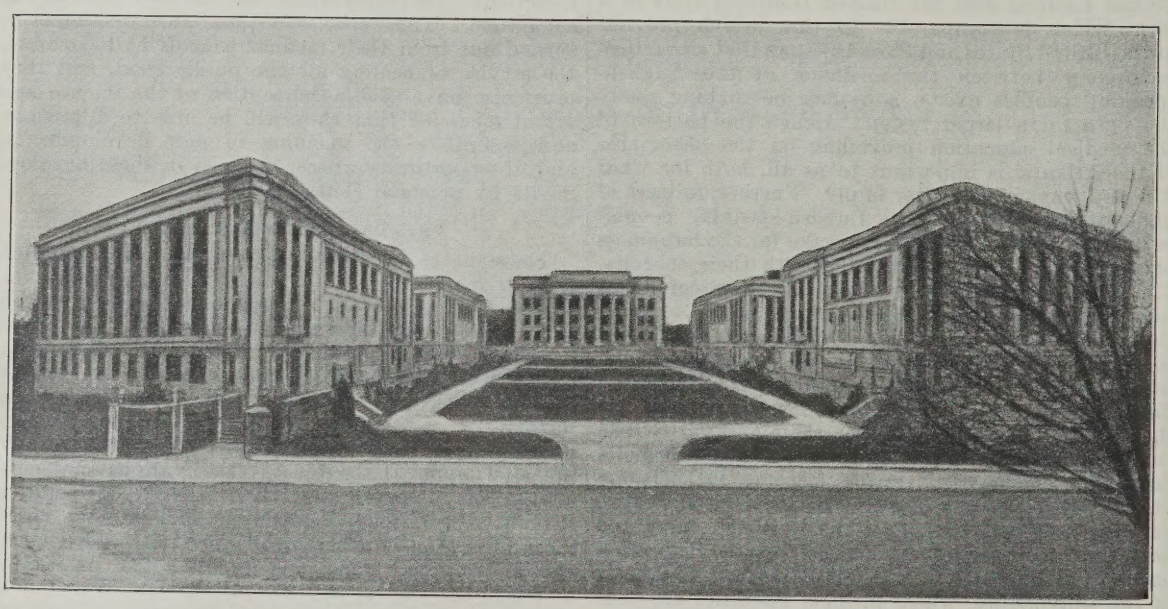
I.—THE MEDICAL SCHOOL OF HARVARD UNIVERSITY.

Historical.

THE course in medicine, established by Harvard University in 1782, was given in buildings of the College, University Hall, and Holden Chapel from the date of establishment until 1810, when the classes were transferred to Boston. In 1816 the first medical school building was erected, while until as late as 1906 the school was situated in the buildings now used by Boston University in the centre of the city; but in 1906 the University completed a notable group of white marble buildings on Longwood Avenue for the occupation of the school. The appearance of the school, owing not only to its structure but to the material employed, can only be described as magnificent (Fig. 1); the use, however, of white marble, not in the original design, was due to the contractors having so much marble at their disposal that they offered to keep their bargain in this way. These buildings, five in number, stand in 11 acres of surrounding ground in the outskirts of Boston, one being designed for the administration and four for the housing of laboratories and departments for clinical instruction. On the road frontage there has now been placed a beautiful war memorial screen.

The administration building contains the Faculty and dean's offices, the central library, and the Warren Anatomical Museum, a very famous collection of over 30,000 specimens, illustrating normal and pathological anatomy. The museum was founded in 1847 by the great Prof. John Collins Warren.

FIG. 1.—THE HARVARD MEDICAL SCHOOL.



THE MEDICAL CURRICULUM.

Matriculation and Requirements for Admission.

The Faculty of Medicine at Harvard provides for a four years' curriculum as a minimum for the acquirement of the sciences directly ancillary to medicine in the school and for their clinical application in the wards of an accredited hospital; but a pre-medical course is assumed, during which a four years' course in a high school or its equivalent must have been completed, in addition to at least two years' work in college, including general inorganic and organic chemistry, physics, and biology. Almost all entrants come in with an Arts degree after four years in a university.

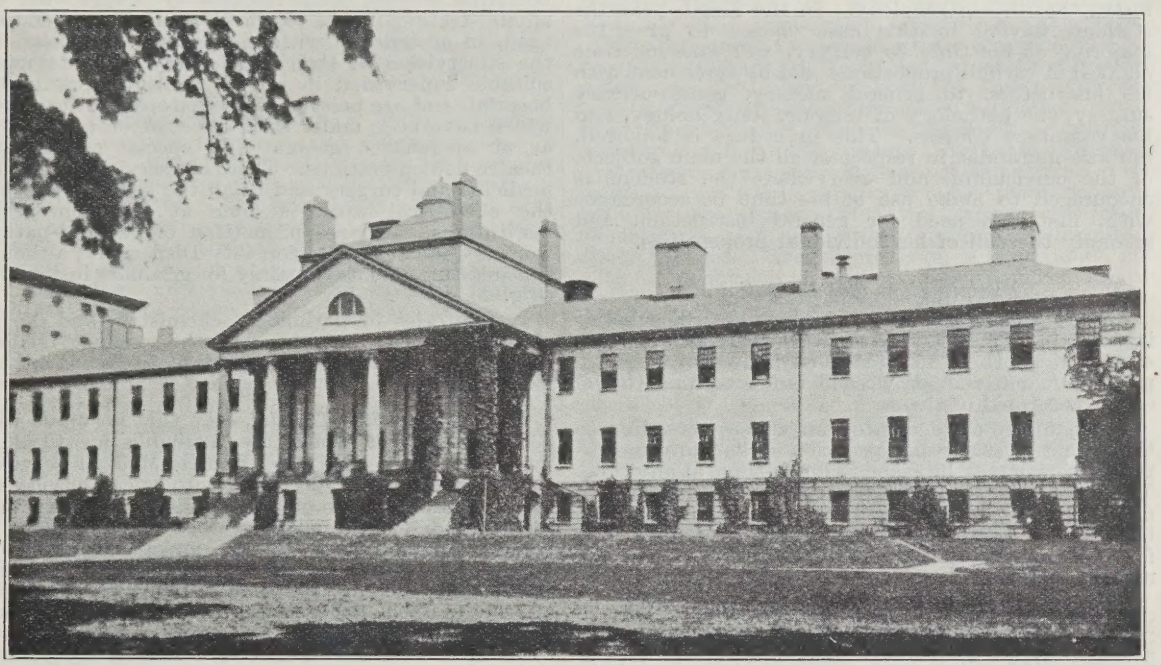
The terminology employed in American universities in setting out their curricula requires a little explanation for British readers. The usual procedures that take place in the American centres are not represented exactly in Great Britain, but just as the objects to be attained are the same so the methods adopted are parallel, though differently named. For example, a high school gives the kind of training that is given in Great Britain at the *public* school, and it is, of course, puzzling to the American to find that the British *public* school is not a State or, as we should say, Board school, but a strictly private establishment. Again, satisfactory evidence of study is provided in America not by simple testamur, but by the production of exact evidence of the time spent in study, as well as details of that instruction. Thus the student desiring admission to the medical school of an American university has to secure "time credits" from his previous school or seminary as proof of his fitness, and this is done by the production of certificates indicating the number of "semester hours" spent to the satisfaction of teachers in acquiring a grounding in selected subjects. A semester hour is one hour of lecture or recitation or two hours of laboratory work per week; as the half year's study is assumed to consist of 16 weeks the duration of the student's actual study can be exactly calculated. To meet the science requirements satisfactorily for admission to any medical school the amount of time credit in an establishment of adequate standing has to be obtained.

At Harvard flexibility in organisation is shown by

the fact that students from other approved medical schools may be admitted to a standing comparable to that they would have held at their original seat of instruction, all matriculation tests having been passed and satisfactory testimonials and time credits produced. Later in the curriculum this process works the other way, for students are allowed, on giving

Second Year.—In this year the time allotted to pathology and neuropathology is large, while more than a commencement of instruction in general medicine and surgery takes place. Anatomy is continued, especially as a study of frozen sections, thus providing a topographical review of the first year's work; bacteriology and physical pathology

FIG. 2.—THE MASSACHUSETTS GENERAL HOSPITAL.



In the Bulfinch building of the Massachusetts General Hospital, in the central dome, the first operation under general anæsthesia produced by the vapour of ether was performed by Dr. W. T. G. Morton on Sept. 30th, 1840.

adequate reasons, to do parts of their work elsewhere than at Harvard, and in this way a Harvard student may acquire something of an international training. Analogous procedures occur at some other educational institutions in the United States.

The candidates for admission to the school largely outnumber those who can possibly be selected, as we shall see to be the case at most of the American universities. Selection is made on general grounds as well as by careful scrutiny of individual claims, but always time credits and proofs of capacity must be produced from proper sources in respect of inorganic and organic chemistry, physics, and biology, with a due knowledge of English, and a reading acquaintance with French or German. The average number of applicants at Harvard during the past five years has been about 400, while the freshman's class has been limited to 125.

SUMMARY OF STUDIES.

The medical course proper extends over four years, while the division of studies is not quite usual, though the logical nature of the scheme is apparent. The length of curriculum is the same as that enjoined by the General Medical Council in Great Britain, as the work of the first year in British schools has to be done in the compulsory pre-medical years at Harvard.

First Year.—The time of the student is divided almost equally between anatomy, histology with embryology, physiology, and biochemistry, but a short course in psychology of distinctly medical bearing is introduced. Half of the time is passed in the dissecting room and half in the histological and embryological laboratories. He must dissect the main divisions of the body to the satisfaction of the demonstrators.

are introduced as well as short courses in obstetrics and pediatrics. The instruction in bacteriology is directed particularly to the consideration of immunity and the problems of infectious disease, the teaching being illustrated by material obtained from the institutions where the later clinical training will be conducted mainly—namely, the Peter Bent Brigham, Massachusetts General, and the Children's hospitals. An early association is thus established between the diagnosis and treatment of disease and is developed by the pathological course. This consists of laboratory work, in connexion with which there are demonstrations of fresh material and museum specimens, and research experiments; while during the entire period groups of students are supervised at various hospitals—those already named, the Boston City Hospital and its adjacent block for contagious diseases, and the Boston Lying-in Hospital.

Third Year.—The student now is mainly occupied with general medicine and surgery; obstetrics and gynæcology are pursued, and there is time allotted for the study of all the usual specialties, the wards both of the great general hospitals and of certain special institutions being available for the purpose. He must take charge of and report on 12 cases in obstetrics under supervision.

Fourth Year.—About 33 per cent. of the time of this last year of study is occupied with medicine and 25 per cent. with surgery, the allotment being reversible at the student's option. The remaining time is divided equally between obstetrics and gynæcology, pediatrics, and "electives"—the term for any branches of medical study which the student may elect to devote additional time to. Life is largely spent in

the wards and can be depicted by an example from what takes place under the heading of surgery. Here, an introductory course in the second year having prepared the students to serve as dressers, they are arranged in small groups in the third year, and serve in the various hospitals under instruction. This takes the form, in addition to ward work, of attendance at theatre clinics where actual patients are shown and diagnosis and treatment discussed over the human subject. There are also lectures and exercises in regional surgery, the whole being accompanied by instruction in rontgenology. In the fourth year the student, having in this case chosen to give the majority of his time to surgery, will find his time allotted in various proportions, and by agreement with his instructors, to general surgery, genito-urinary surgery, the pathology of tumour, rontgenology, and his voluntary courses. This procedure is followed, mutatis mutandis, in respect of all the main subjects of the curriculum, and everywhere the student is encouraged to make use of his time in accordance with, first, his need for general instruction, and secondly the call of his individual propensities.

Examinations and Promotion.

Speaking generally, the procedure described below is general in American universities where students are examined by their own teachers, by whom they are promoted, deferred, or weeded out according to the opinions formed of them.

Students are divided into four classes according to their time of study and proficiency, and any incompetent person may be asked to discontinue at any time. They are examined in each course and marked as determined by each department; they can anticipate the regular course of examinations and they pay fees for each additional examination incurred as the result of failure.

The instructors in the principal courses during the year hold a promotion board for each of the first three years. These boards mark each student for the corresponding school year, promote those who have satisfied the tests, interview, examine, and if necessary warn weak candidates, and have the responsibility of advising students to withdraw. The action of the boards appears to be final, but is not taken without due consideration. A student failing in two major subjects in one year will have to withdraw from the school, while passing in all the subjects at the minimum grade will not earn promotion. Failure, when not entailing rejection, puts the student under a "condition," and he cannot, in ordinary circumstances, proceed with the curriculum until the condition is removed by a successful re-examination. The promotion opportunities, however, are considerable, while chances for re-examination, sometimes of a special nature, are given.

Finally the committee on examinations gives a general examination to each candidate for the degree of M.D. and reports to the Faculty for graduation those properly qualified for the degree and for honours. The general examination consists of practical tests along all the line, including adequate clinical use of the medical sciences; and a student who fails to satisfy the examiner on three occasions is debarred from further attempts.

HOSPITAL TRAINING.

In 1810 the Medical School of Harvard was transferred from the suburb of Cambridge to Boston in order to secure the clinical facilities of the city. These facilities may be regarded as proportional to the number of patients in the hospitals who, being under the care of instructors on the staff of the medical school, are available for teaching purposes; and on this basis the school is closely affiliated with the hospitals now enumerated, three of which have been specially named already. Under the educational scheme each student comes into contact, under supervision, with patients in these hospitals from the second half of his second year until the close of his course, this contact becoming more intimate as the course proceeds.

The Massachusetts General Hospital.—The Massachusetts General Hospital was founded in 1813 and has been associated with the school since the foundation. It contains now 520 beds. A recent extension of the out-patients' department has connected up the Massachusetts Eye and Ear Infirmary with the general activities of the hospital, while the Nurses' Home, standing on the other side of one of the four bounding streets, communicates by tunnel with the administration block. Medical students are encouraged, in accordance with the pattern laid down for the supervision of their studies, to coöperate under suitable supervision in all the routine work of the hospital, and are present at the autopsies of the cases which have been under their direct attention. as well as at operations, general and special clinics, and theatre demonstrations. There are services in general medicine and surgery and in all the specialties, while the obstetrical work is done at the appropriate institutions. A large proportion of the out-patient work is done at the Boston City Dispensary, although this institution is used mainly for graduate instruction (Fig. 2).

Laboratories in pathology, chemistry, and X ray are maintained, and there is an excellent medical library, all of which are open to students in the Medical School.

The Boston City Hospital.—At this hospital, with 939 beds, all of which are available for teaching purposes, the Second and Fourth Medical services, the Fifth Surgical, and the Neurological service are under the direction of professors at the Harvard medical school. In addition there are divisions of pediatrics, gynæcology, and so on, open to students. In the out-patient department new patients furnish additional teaching material. Clinical laboratories are maintained for research, pathology, nephritic, diabetic, blood, pediatric, and neurological work, and basal metabolism. The X ray service is very large and important. There is an excellent library, including 73 current medical journals.—*The Boston City Hospital, South Department.* This hospital is for contagious diseases and occupies a block by itself adjacent to the Boston City Hospital proper. It has a capacity of 338 beds and has abundant material for clinical instruction. Students make ward visits three or more times a week. During the year 1926 there were 1787 cases treated, of which 813 were scarlet fever and 266 were diphtheria.—*Hospital Department: Sanatorium Division.* The Boston Sanatorium for tuberculous patients at Mattapan has recently become a part of the Boston City Hospital. It has a capacity of 422 beds and a daily average of 373 patients. During eight months of the year two to four fourth-year students of Harvard Medical School spend eight hours daily for one week in this hospital under the supervision of the resident physician.

The Peter Bent Brigham Hospital.—This hospital has been closely associated with the Medical School since its dedication in 1913. It is for general medical and surgical cases, and is situated on grounds adjacent to the medical school buildings. There are 246 beds, all of which are used for teaching purposes. There is also maintained an out-patient service for ambulatory medical and surgical patients to which 6192 new patients applied during the past year. There are well-equipped medical, surgical, and pathological laboratories. The hospital, by special arrangement, makes use of the library of the medical school.

The Children's Hospital.—This hospital, adjacent to the school, maintains a medical, surgical, orthopædic, nose and throat, and a well-babies clinic. There are 211 beds, of which 165 are available for teaching purposes. Well-equipped laboratories are provided for the study of material from the wards and out-patient service.—*The Infants Hospital (Thomas Morgan Rotch Jr. Memorial Hospital for Infants)* is

adjacent to and under the management of the Children's Hospital. There are 66 beds, all of which are available for teaching.

The Boston Lying-in Hospital.—This hospital occupies a building in Longwood-avenue, and of the 100 beds 65 are used for teaching. In the out-patient department, 1250 cases were attended last year. under supervision by third- and fourth-year students. A well-equipped laboratory is available.

The Free Hospital for Women, devoted exclusively to the surgical treatment of diseases peculiar to women, has a capacity of 94 beds, of which 74 are available for teaching, and a large out-patient department. Library and laboratory facilities are available.

Boston Psychopathic Hospital, a State institution for acute, curable, incipient, and doubtful cases of mental disease, has 110 beds, all of which are available for teaching, and receives patients at the rate of about 1800 a year. The hospital is equipped with psychological, neuropathological, and biochemical laboratories. The out-patient department receives patients at the rate of 1000 a year. In addition to the psychoses and neuroses the clinical material includes cases of mental defect and instability, and of delinquency.

The Massachusetts Eye and Ear Infirmary.—There are 209 beds in this hospital, 167 of which are used for instruction in diseases of the eye and ear. Nose and throat out-patient operations are done at the Massachusetts General Hospital. Pathological and X ray laboratories are maintained.

The Collis P. Huntington Memorial Hospital and the J. Collins Warren Laboratory of Bio-Physics.—This hospital and laboratory of the Cancer Commission of Harvard University afford opportunity for the study of human tumour cases. The 22 beds are all available for teaching purposes, and the aim of the hospital is to study special problems, more particularly in relation to early diagnosis.

II.—THE MEDICAL COLLEGE OF CORNELL UNIVERSITY.

Historical.

THE Medical College of Cornell University was established in 1898, when Colonel Oliver H. Payne gave several million dollars to the University for this purpose. The college was organised largely through the earnest efforts of Dr. William M. Polk, who became the first dean. It was established in New York City, which is about 300 miles away from Ithaca, N.Y., the seat of Cornell University, in order that the clinical facilities of the great municipal hospital and other institutions in New York should be enjoyed by the students. To bring about a closer coördination of the work at the University at Ithaca with that of the college, the various subjects comprising the first two years of study were offered both in Ithaca and in New York. Later the work at Ithaca was reduced to that of the first year, and departments of anatomy physiology, and biochemistry are maintained. All students are combined for the work of the second and subsequent years in New York.

The principal building is located immediately close to Bellevue Hospital, the main municipal hospital conducted by the City of New York. In this building are housed the departments of anatomy, physiology, biochemistry, pathology, bacteriology, and clinical pathology. The medical library, supplied with the more important medical periodicals in French and German, as well as in English, is also located in the main building. In this building is also the Cornell Clinic (Fig. 3), an out-patient department where all branches and specialties of medicine and surgery are represented. Over 140,000 visits are made to the out-patient department annually, which supplies an important part of the clinical training, and being in close contact with the various laboratory departments of the school, it furnishes material for research as well as for instruction. The Loomis Laboratory, a large building adjacent, affords quarters for pharmacology, experimental therapeutics, experimental surgery, and other fields of teaching and research.

In June, 1927, an agreement was entered into between the Medical College and the New York Hospital, forming the New York Hospital-Cornell Medical College Association. According to the terms of this agreement the two institutions are merged. A group of buildings are being planned which will afford a new and large plant for both the hospital and the college, overlooking the East River, adjoining Rockefeller Institute for Medical Research. Additional endowments have been secured by each institution concerned in the merger, and the entire activities of the medical school will be conducted in this plant. Separate buildings are designed for the various laboratory departments, and the hospital as planned will contain about 875 beds. Special provision is being made not only for medical and surgical departments, but also for psychiatry, obstetrics, and pediatrics. The Association is operated under the supervision of a joint administrative board composed of three governors of the New York Hospital, three representatives of the Trustees of Cornell University, and one other member elected by the appointed members. A director of the Association has been appointed in order to coördinate the activities of the medical school and hospital, and the Faculty and hospital staff are to form one body organised on a university basis.

THE MEDICAL CURRICULUM.

Matriculation and Requirements for Admission.

All students are required to have obtained the bachelor's degree or to be already seniors. In the latter case they have completed three years of college work, and are granted the bachelor's degree by the institution in which this work was done after completion of the first year in the Cornell college. Students are also admitted to the Cornell college who give evidence by examination of having acquired an education equivalent to that required for the bachelor's degree. Practically all students, however, enter after having had three or four years of college work, which must include, as a minimum, two years of chemistry, one year of physics and biology, and adequate training in at least one modern foreign language, preferably French or German. The classes are limited to 65. Students from other recognised medical schools are admitted to advanced standing when there are vacancies in the class to which they desire to enter.

SUMMARY OF STUDIES.

The medical year extends over eight months, from October to June. It is divided into three terms of approximately 11 weeks each. During the *First Year* courses in anatomy, biochemistry, and physiology are pursued. During the first two terms of the *Second Year* physiology, pathology, and bacteriology are the main subjects studied, with a few hours devoted to elementary medicine and surgery. During the third term of the second year pharmacology is studied, bacteriology and pathology are continued, more time is given to medicine and surgery, and introductory lectures to some of the special branches of medicine and surgery are held.

With the beginning of the *Third Year* instruction is largely confined to the clinical subjects, although pathology and pharmacology are continued. Instruction in public health is taught throughout the third year. All the work of the *Fourth Year* is done in the various hospitals and out-patient departments, controlled by or affiliated with the Medical College. For this purpose the students are divided into groups

of about ten students. These groups rotate through the various teaching services in the hospitals and out-patient clinics.

Examinations and Promotions.

Students are advanced in the course from one year to the next upon recommendation by heads of departments after examination in the work of that year, but examinations may, at the discretion of the head of the department, include all the work previously covered in the year or years preceding the examination in question. Examinations are held at the close of each academic year, except that in each course extending through a part of the year only the examination may be held at the close of the course.

A student who fails to pass more than 40 per cent. of the work of the first and more than 30 per cent. of the work of subsequent years is required to withdraw from the school. Students failing to pass less than these percentages of their work are re-examined at the opening of the following session. If they then fail to pass they are required to withdraw from the school. Under special but rare conditions, however, students may be permitted to repeat a year's work.

HOSPITAL TRAINING.

Clinical instruction is given in a number of hospitals, some of which are closely affiliated with the Medical College.

The New York Hospital, the oldest hospital in New York, has entered into an agreement with the school which assigns the pathological and half of the entire medical and surgical services to the Cornell University Medical College for the advancement of its teaching and research. The services of the New York Hospital are very active, and about 100 beds are available for the purposes of Cornell students. The staffs of these services are nominated by the Cornell Faculty.

Bellevue Hospital, situated directly across the Avenue from the Medical College, contains 1200 beds. The hospital is organised in four divisions, one of which has been placed by the trustees of the hospital at the disposal of the Cornell Faculty for medical instruction, which nominates the staff and assumes full responsibility of the clinical work. (See p. xi.)

Memorial Hospital is devoted to the study and treatment of cancer. The Cornell College is responsible for the medical and surgical activities of the hospital and nominates the professional staff. This hospital contains about 100 beds.

Clinical facilities are also afforded by the John E. Berwind Maternity Clinic, the New York Nursery and Child's Hospital, the Neurological Institute, the New York State Psychiatric Institute, and the Manhattan State Hospital for Mental Diseases.

FIG. 3.—THE CORNELL UNIVERSITY MEDICAL CLINIC.

III.—THE MEDICAL SCHOOL OF COLUMBIA UNIVERSITY:

COLLEGE OF PHYSICIANS AND SURGEONS.

Historical.

Columbia University was founded in 1754 by a grant from George II. of England, as King's College "for the instruction of youth in the learned languages and the liberal arts and sciences." The College organised a Medical Faculty some 20 years later and was the first institution to confer the degree of M.D., Robert Tucker and Samuel Kissam being the earliest graduates. In 1784, after the Revolution, the College was reorganised and named Columbia College of New York. In 1814, the re-established Medical Faculty of the College was merged in the College of Physicians and Surgeons, but until 1891 the conjunction was only nominal—since when, however, it has been definite. The College has just moved, to become an integral part of the new Medical Centre, a huge and imposing group of buildings on the bank of the Hudson River.

The Medical Curriculum.

Matriculation and Requirements for Admission.

A collegiate course of four years, terminating with a degree, is the most desirable preparation, but the minimum requirement accepted is attendance for two full years of at least seven months at a collegiate institution acceptable to the University. The subjects at which study by the students for certain hours is required are: physics, inorganic and organic chemistry, biology, and for two years at least English and either French or German. The time which this study has taken is calculated in semesters, and the credit requirements are very strictly adhered to, especially in the case of the admission of special students and those who desire to join as of advanced standing. The average admissions total about 12 per cent. of the applications. No students have been admitted for the last three years who have not to their credit at least three years of college work.

This pre-medical education can also be taken not only at other universities—the Rochester, the Colgate, and Hobart and Ripon Colleges may be mentioned—but can be carried out partly in a combined course with Columbia College. These universities give the M.B. degree to students, who after three years of work with them complete the other year in medicine in Columbia. We may note again the flexibility in reference to the admission of students, native or foreign, to advanced standing in the curriculum after the production of proper credentials, but any such student will be required to submit to examination at the pleasure of the Faculty.

Summary of Studies.

The following is an outline of the work required of the candidate for the degree of Doctor of Medicine during the four years of actual medical study. Each year is divided into three trimesters, the first two years as follows: Sept. 26th to Dec. 6th; Dec. 7th to March 1st; and March 9th to May 18th.

First Year.—The *first* period covers instruction in the elements of anatomy and histology, coupled with work in the laboratory and lectures; while the student is also introduced to biochemistry. In the *second* period, while anatomy is continued and special attention is being paid to neurological anatomy, physiology and biochemistry are the main subjects. The *third* period reviews both physiology and anatomy, the latter especially in the gross.

Second Year.—The *first* period is occupied in the study of pathology and bacteriology, both in the laboratory and through daily lectures. In the *second* period, of full three months, while pathology is continued and developed, the student is introduced to surgery and the art of physical diagnosis. In the *third* period, the continuation of surgery is associated with clinical pathology, psychopathology and pharmacology are introduced, as well as the principles of internal medicine. It should be noted that under the heading of pharmacology is included instruction not only in the action of drugs but in the elements of animal research. This is an invariable rule, and the same connexion is maintained in physiology and anatomy.

Third Year.—In the third, as also in the fourth year, the students are divided into groups, with an eye to a logical order of the main themes and the coördination of the work of each department. The education proceeds in the wards provided by the Medical Centre. There are theoretical and clinical lectures, demonstrations, and clinics in medicine and surgery, gynæcology, neurology, and practically all the important specialties which require particular study. The classes are divided into small groups for instruction in physical and medical diagnosis, and for practical work in the specialties.

Fourth Year.—During the fourth year, various groups of students attend for clinical instruction the wards especially of the Presbyterian and Bellevue Hospitals; while the obstetrical course is carried out at the Sloane Hospital for Women. Practically the whole of this year is spent in hospitals and institutions, mostly affiliated to the new Medical Centre, bedside instruction largely taking the place of general and clinical lectures. The students come into closer contact with the patients in order to apply the various diagnostic methods they have been studying. They learn how to take the history of the case, to arrive at diagnosis and prognosis by complete physical examination and watching the progress of cases, in the course of which they are expected to have an opinion upon treatment. It will be seen that this is a more precise way of stating that in the wards of the hospital the students carry out the duties of clinical clerks and dressers. Out-patient instruction is given at the Vanderbilt Clinic, where exceptional opportunity is afforded for studying all forms of acute disease in infants and young children. But all branches of medicine are represented at the Vanderbilt Clinic, which is the combined out-patient department of all the hospitals at the Medical Centre.

Much attention has been spent at this school over the instruction of students in the diseases of children, and teaching in the fourth year has now been largely concentrated at the Babies and Bellevue Hospitals. A follow-up clinic, established at the latter, offers another teaching resource, as the student is instructed in the management of the congenitally syphilitic child. Similar work is done at the Sloane Hospital, where also there is a follow-up clinic for premature infants. The student, it will be observed, therefore, is here introduced practically to the duties of social service.

Examinations and Promotions.

The procedure already noted in dealing with the medical course at Harvard University is adopted—with differences of detail, and with various assumptions of authority or displays of discretion and sympathy—at all the university medical centres. For a system of set tests at stated intervals by external examiners there is substituted one of continuous inspection under which students who fall behind their classes are dealt with. The regulations at Columbia may be reproduced as showing the general procedure regulating a student's advancement.

1. A student is not allowed to go on with his class who has failed in any one of his courses until he has removed that failure to the satisfaction of the head of the department.

2. (*a*) A student who has failed in two courses in the first year may be allowed re-examination in the two failed courses, provided that the two failures do not include both anatomy and biological chemistry.

(*b*) A student who has failed in two courses of the second, third, or fourth years may be allowed re-examination in the two failed courses, provided that

the total hours of the two courses failed in do not exceed 33⅓ per cent. of the total course hours for that year.

3. A student who has been allowed re-examination and has failed in the re-examination must repeat the entire work of that year.

4. A student may repeat an entire year only once during his medical course, and may not repeat any other year later unless the Faculty of Medicine votes to suspend this rule in his case on the recommendation of the Class Faculty under which the student has been working.

FIG. 4.—THE MEDICAL CENTRE FROM THE HUDSON RIVER.

Left to right—the Psychiatric Institute and Hospital, School of Nursing, and combined Medical School and Hospital building.

HOSPITAL TRAINING.

The Medical Centre.

A permanent affiliation between Columbia University and the Presbyterian Hospital was accomplished in 1921. The two institutions have erected new buildings in close geographical and functional relationship on the large plot of land given to Columbia University and Presbyterian Hospital by Mrs. Stephen V. Harkness. This plot extends from 165th-street to 168th-street and from Broadway to Riverside Park, comprising about 20 acres.

In addition to the College of Physicians and Surgeons and the Presbyterian Hospital, the following institutions are represented at the Medical Centre: the School of Dental and Oral Surgery, Presbyterian Hospital School of Nursing, DeLamar Institute of Public Health, the Sloane Hospital for Women, the Squier Urological Clinic, the Vanderbilt Clinic, the Babies Hospital, the Neurological Institute, the New York State Psychiatric Hospital and Research Institute. This arrangement of buildings brings the various schools connected with medicine and allied subjects in close physical connexion with the hospitals, clinics, and institutes in which clinical instruction is carried on.

Presbyterian Hospital.—The Presbyterian Hospital, one of the general hospitals of New York City, was founded in 1868 for "the poor of New York City without regard to race, creed, or colour." Under the terms of its affiliation with the Columbia University staff, members of the hospital are appointed by the Board of Managers on nomination by the trustees of the University, and every member of the hospital staff is a member of the staff of the medical school. The hospital occupies a 22-story building. In this are the wards of the medical and surgical services, the Sloane Hospital for Women, the Squier Urological Clinic, as well as operating rooms and several floors of housing.

Sloane Hospital.—The Sloane Hospital for Women was built at 59th-street and Amsterdam-avenue, and presented to Columbia University by Mr. and Mrs. William D. Sloane in 1886. In the new buildings it occupies three floors of the main hospital building. The wards of the hospital furnish 128 beds for obstetrical and gynæcological cases. Patients, other than emergency cases, are admitted to the hospital through the ante-partum and follow-up clinics of the hospital, or the Gynæcological Department at Vanderbilt Clinic. The hospital is under the direction of the Department of Obstetrics and Gynæcology, the executive officer of the department being the director of the hospital. The assistant professor, associates and instructors are the attending obstetricians and gynæcologists. The resident and assistant resident obstetricians and gynæcologists are also instructors in the department. Internes of the hospital serve for one year, and are selected from men who have already completed a term in a general hospital. The laboratory work of the hospital is carried on in conjunction with special laboratories of the Faculty. The heads of the various special departments in the Faculty are consultants of the hospital, and the attending physicians in the specialties are appointed from these departments. The deliveries in the hospital number about 1800 a year. The gynæcological service is run in conjunction with the gynæcological service of the Vanderbilt Clinic, and the attending obstetricians and gynæcologists of the Sloane Hospital are in charge of the clinic. The Social Service Department of the hospital keeps in close touch with patients applying for treatment, thus making it possible for students to study the end-results of operative cases and

prenatal, intra-partum and post-partum care of obstetric cases. The care of the infants is supervised by the attending pediatrician.

The Squier Urological Clinic.—The Squier Urological Clinic occupies the entire eighth floor of the new hospital building. It is comprised of wards of 12, 5, and 4 beds, and contains a large number of single rooms for surgical cases in urology. The clinic is under the direction of the Department of Urology, the executive officer of the department being the director of the clinic. The assistant professor, associates and instructors are attending surgeons, and the resident and assistant resident are also instructors in the department. There are laboratories on the same floor, for the exclusive use of the Squier Urological Clinic, fully equipped to do diagnostic, X ray, bacteriological, pathological, fluoroscopic and research work, necessary for the care and treatment of patients. There are two large, especially equipped operating rooms and surgical clinics are held by the attending staff, throughout the year. The out-patient department of the clinic is situated in the Vanderbilt Clinic, and is under the direction of the attending staff of the Urological Hospital. The out-patient department is fully equipped for cystoscopic, X ray work, fulguration, diathermic and laboratory work. The Harkness Pavilion is available for the accommodation of private patients of the attending staff.

The Vanderbilt Clinic.—The Vanderbilt Clinic, presented by the Vanderbilt family to Columbia University in 1888, has become the common out-patient department for all the hospitals affiliated in the Medical Centre, and is a fully equipped dispensary for the sick poor. It affords ample material for extended practical clinical instruction in the various departments of medicine, as the professors, with their clinical assistants, have the entire charge of its

IV.—THE MEDICAL SCHOOL OF NEW YORK UNIVERSITY:

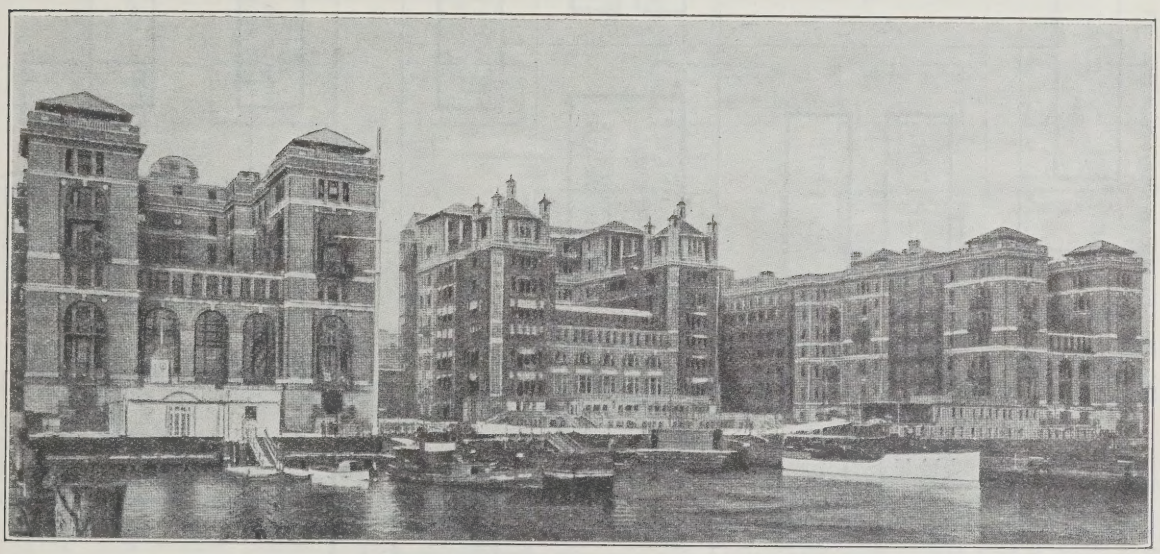
BELLEVUE HOSPITAL MEDICAL COLLEGE.

Historical.

THE University was established in 1898 by the Union of the University Medical College and the Bellevue Hospital Medical College. Instruction was first given in the former in 1841 and in the latter in 1861. The College occupies five large buildings diagonally opposite to Bellevue Hospital, and is officially known as the University and Bellevue Hospital Medical College.

The College building was erected by the Medical Faculty of Bellevue 30 years ago to meet increasing demand for such facilities and was transferred to New York University at the time of the consolidation. Adjoining it is the Carnegie Laboratory, a gift to the Bellevue by the late Andrew Carnegie. The main building, six storeys high, accommodates part of a vast clinic for the outdoor sick poor, while on various floors are research laboratories, working libraries, with an anatomical department on the top floor, having well-lighted and ventilated dissecting-rooms. The Carnegie Laboratory was extended some 20 years ago, again by the gift of Andrew Carnegie, while a large laboratory has been erected to serve as a centre for hygiene and public health. Part of the new laboratory and of the Carnegie Extension serve as an immense out-patient clinic for general medical and surgical cases, diseases of women, and various special pathological conditions. It will be seen that an almost unlimited amount of clinical material lies under the hand of the medical students of the College.

FIG. 5.—BELLEVUE HOSPITAL FROM THE EAST RIVER.



practice. The building is so arranged that each department has rooms for practical instruction to students in small sections. All modern appliances for the treatment of diseases have been introduced, so that students can learn the modern technique in each of the special departments of medicine.

St. Luke's Hospital is a general hospital of first-class standing, with 411 beds, while *St. Mary's Hospital*, a free hospital for children, has 134 beds. Out-patient attendance is optional at either institution.

The Neurological Institute and the *Babies Hospital* are in course of construction and new buildings will house these two institutions. It is expected that both will be completed during the coming academic year.

THE MEDICAL CURRICULUM.

Matriculation and Requirements for Admission.

The minimum requirement for admission to the University is 72 semester hours of college work, all of which must be of a sort to count for a baccalaureate degree. This period is divided up into the times of study allotted to chemistry, physics, biology, English composition and literature, and a reading knowledge is demanded of one of the four great European languages—French, German, Italian, and Spanish. Where the applicant has reached all but the last year of university graduation, part of his medical training will count as a fourth year at his university. But while these constitute the minimum requirements for entrance, it is considered that a college course of four

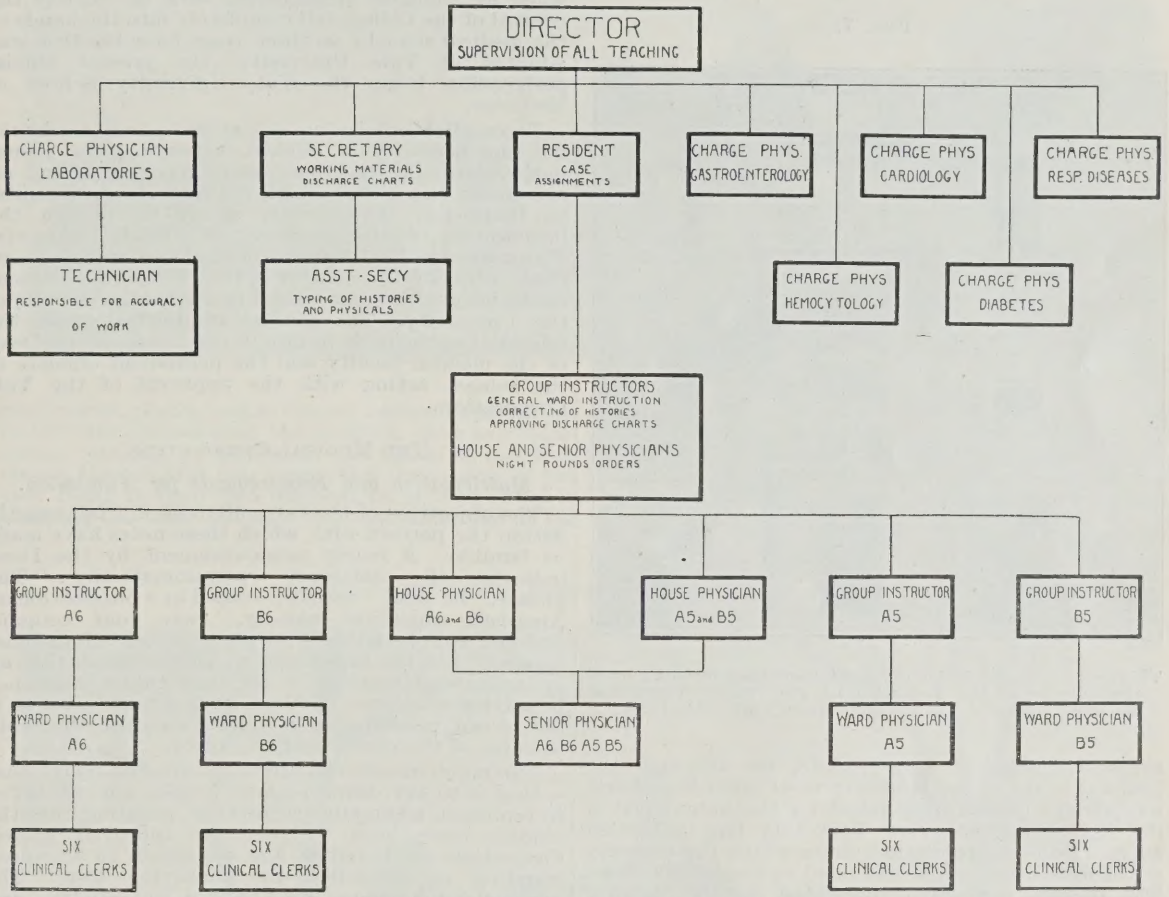
years is the most desirable preparation for the study of medicine, so that preferential consideration, when the students are selected, is given to those of higher scholarship attainment. During the past four years only one student has been admitted who was not eligible for a bachelor's degree at the end of his first medical year. This point should be noted, as the pressure on the school is very high, the last figures being 125 men selected out of 800 applicants.

The same flexibility prevails here as at the Cornell and Columbia Universities, inasmuch as successful students in other colleges are eligible for admission to advanced standing, save in the final year.

satisfactorily completed laboratory courses in normal and pathological histology, and bacteriology, chemistry, physiology, and pharmacology, while they must also have completed their work of dissection. In addition to the certificate in respect of laboratory courses, they must pass examinations in the subjects mentioned, and then further weeding-out takes place.

Third Year.—In the third year the time is mainly occupied by the general study of surgery, medicine, and physical diagnosis, although a reasonable proportion of time is devoted to obstetrics and gynæcology. With the exception of rontgenology, special neurology, and psychology, all the special departments of medical

FIG. 6A.—TEACHING ORGANISATION AT THE BELLEVUE HOSPITAL.



The interrelation between the clinical and teaching duties of the staff will be followed at once on understanding that the assistant physicians in the previous schema are the group instructors in this schema.

SUMMARY OF STUDIES.

The following outline shows the work required of the candidate for the degree of Doctor of Medicine during the four years of actual medical study.

First Year.—This period covers instruction in anatomy, microscopic and gross, and the principles of physiology; teaching develops the pupil's knowledge of chemistry and introduces physiology. Before admission to the second year's study the student must present evidence of having satisfactorily completed the relevant laboratory courses, as well as pass examinations in these subjects. Here the weeding-out process by the instructors begins to take place.

Second Year.—The main subject of the second year is pathology, while physiology is continued, and pharmacology, with its associated study of animal research, is brought into the curriculum. The other teaching, both formal and practical, covers bacteriology and immunology, while the groundwork is laid in applied pathology and surgery. The students cannot enter the third year classes until they have

science are brought to the notice of the students, who cannot enter the final year of study until they have passed written examinations upon these subjects and practical examinations in gross and applied pathology.

Fourth Year.—The time of the fourth year, being spent practically in the wards of the Bellevue, is largely devoted again to surgery, medicine, gynæcology, and obstetrics, but considerable stress is laid at this period upon pediatrics and neurology. At the end of the fourth year the student passes examinations, written and practical, in these various subjects, while his standing is also influenced by the record of his work in classes or wards.

Examinations and Promotions.

At the end of each of the four years of the curriculum the standing of the student is determined by written and practical examinations and by records of work in laboratory or hospital ward. The students are advanced from one year to the next in accordance with the results at the close of each session, and the work of

each year is separately considered, those who fail to pass examinations satisfactorily at the close of any period being unable to proceed to the next period until re-examination at the beginning of the new college year has justified the promotion. Repeated failure implies rejection from the school.

HOSPITAL TRAINING.

The Bellevue Hospital.

The students of the Medical Faculty of New York University are ranged under the Third Medical Division of the hospital, the Second Medical Division comprising the Cornell students, in dealing with whom general notes on the institution were made. But those

FIG. 7.

This doorway in the Bellevue Hospital buildings formed part of the Balcony of the Federal Hall over which Washington delivered his first Inaugural Address on April 30th, 1789.

notes will soon be out of date, for although the hospital is one of the largest in the United States and has always been distinguished for the abundance of its clinical material, New York City has authorised an enormous appropriation under which the capacity of the institution will be extended to nearly 2000 beds. The present appearance presented by the hospital from the East River shows its imposing character.

The members of the Faculty, who are attending physicians and surgeons to the hospital, hold regular clinics for students in the large theatres, and small sections of the classes are taken into the wards to examine medical and surgical patients. Students of the fourth-year class are regularly assigned to the care of cases in the wards under the supervision of the attending and house staffs. Many of the great charitable institutions receive their convalescing or chronic inmates through Bellevue Hospital or its out-patient department, in which more than 75,000 new patients a year are treated.

There is within the College building a medical and surgical dispensary, affording abundant material for practical clinical instruction connected with which are all the necessary laboratories, including a fine X ray department.

The diagrams given herewith set out the clinical and teaching organisations under which the Third Medical Division operate at the Bellevue Hospital, from which it will be seen how intimately the instruction of the students is a definite part of the management of the hospital.

V.—THE MEDICAL SCHOOL OF YALE UNIVERSITY.

Historical.

THE school of medicine was organised initially as early as 1710, when a charter was granted by the Connecticut General Assembly for the Institution of Yale Medical College, to be conducted under the joint supervision of its own President and the Connecticut Medical Society. Although the institution was formally opened in 1813, the medical school of Yale College did not take its real shape until 70 years later, when by amicable arrangement with the society the control of the College fell completely into the hands of the medical school; so three years later the title was adopted of Yale University, the present official designation being the Yale University School of Medicine.

The medical curriculum was at first purely academic, but the necessity of clinical instruction for proper medical training had been early recognised, and an agreement was come to with the New Haven Hospital to that end. As recently as 1914, through the beneficence of the Anthony M. Brady Memorial Foundation, a fund was established and an agreement made whereby the control of the clinical department of the hospital became vested in the medical faculty of the University. The general administration of the school of medicine is to-day in the hands of the Dean of the medical faculty and the permanent officiate of the school, acting with the approval of the Yale Corporation.

THE MEDICAL CURRICULUM.

Matriculation and Requirements for Admission.

The objectives of the curriculum do not fall exactly within the pattern with which these notes have made us familiar. A recent pronouncement by the Dean indicates the difference epigrammatically: "The phrase," he said, "recently coined in a publication on American education, namely, 'Save your coupons and get a diploma,' has no place in our educational system," and the experience at Yale indicates that an inelastic stratification of the curriculum may not be advisable. None the less, such definite plan as is laid down presents, as it must, some of the main features of the plan at other centres.

The requirements for admission are the usual ones—that is to say, three years of college work are taken to represent adequate preparation, granting that the studies have been followed in approved places. Credentials are required, and admission to advanced standing is controlled by qualifying tests. The compulsory subjects are physics, chemistry, and biology, together with mathematics taken up to a point where the elementary principles of the calculus can be comprehended. Importance is attached to humanistic studies, and a knowledge of English, and of French and German up to a point, is expected.

Under the general plan, the subjects of the medical and biological sciences are arranged in two groups, those embracing the basic subjects and those which deal particularly with clinical medicine; when the students have decided upon which field they intend to enter they can elect to take courses accordingly. These courses are divided into two periods of rather more than two years, the first of which, that devoted to basic study, is common to all the students, while the second period is employed in special directions.

SUMMARY OF STUDIES.

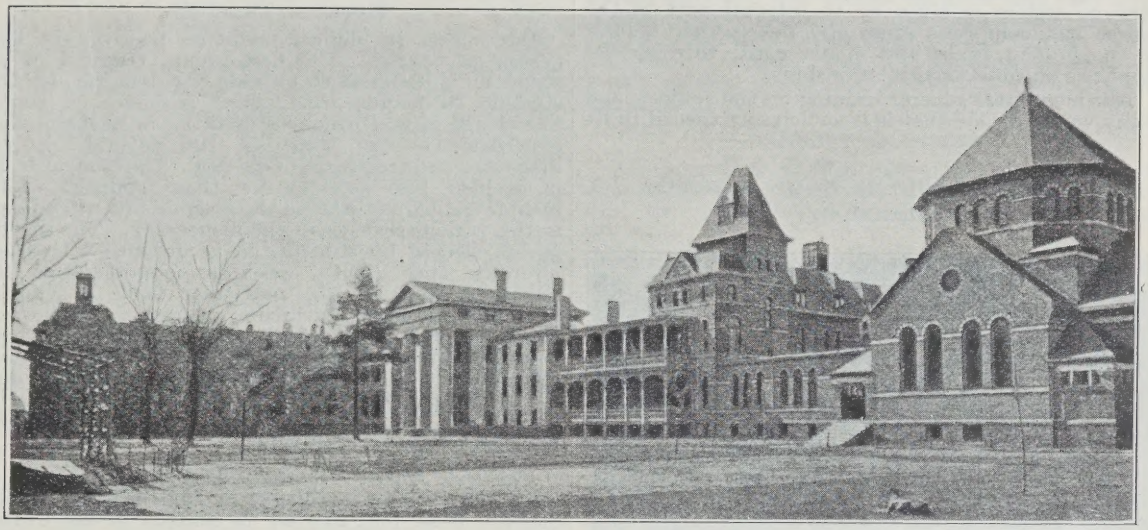
The First Period.—Ordinarily, students take the subjects of anatomy, physiology, and physiological chemistry before the subjects of pathology, bacteriology, and pharmacology; but the students, on testing, are allowed to arrange their curriculum in accordance

with their previous training and their personal bent, under a system of electives.

The Second Period includes the broad field of clinical medicine, training being here given at

It will be seen that the course cannot be reduced to any pattern similar to the routine of education laid down elsewhere, while it puts a premium on the student, at the very commencement of his career, who knows what he

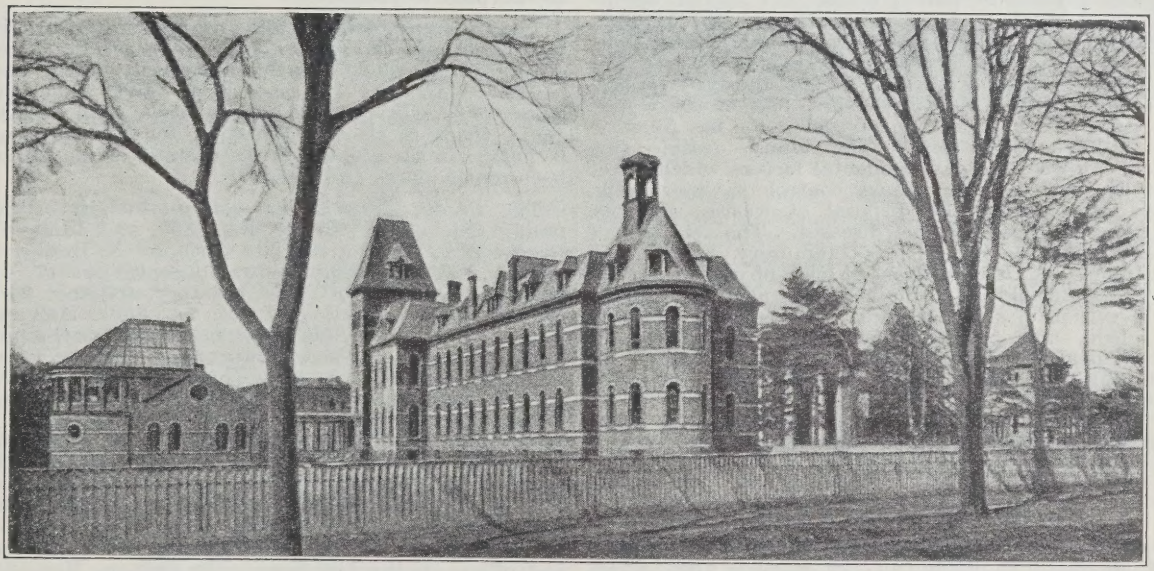
FIG. 8.—NEW HAVEN HOSPITAL FROM THE NORTH-EAST.



conferences, clinics, and in the out-patient department. In the first clinical year the students serve as clinical clerks, rotating by section in the wards of the New Haven Hospital for two terms, the third term of the year being at their own disposal, to be used either in studying the basic subjects or in pursuing one of the

wants. To such an intending doctor the freedom in electing the places where he wishes to concentrate will be a great stimulus, but the responsibility on the authorities who permit him to exercise such discretion is proportionately great. To take two examples. Under the heading "Anatomy," the student has to

FIG. 9.—NEW HAVEN HOSPITAL FROM THE SOUTH-EAST.



branches of clinical medicine, that is, internal medicine, general surgery, gynæcology and obstetrics, or any of the various specialties.

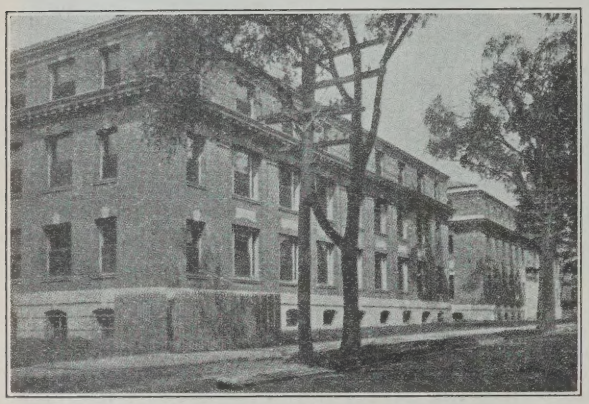
During the second clinical year, students rotate in the out-patient department while using still larger opportunities to take elective courses; indeed, it seems possible for a student to spend the major part of the concluding phase of his training entirely in elective work.

satisfy the demands of a required course during his first two terms. It is chiefly a laboratory course under the supervision of instructors, with conferences correlated with the laboratory work. Gross, microscopic, and developmental anatomy are so combined that the student, while working on the gross anatomy of a part, studies also its microscopic structure and developmental history. In this way a complete picture of an anatomical region is obtained. Two

students dissect an entire cadaver, each being assigned to a lateral half, and all the students will be found working on the same part at the same time. The microscopic structure is studied by means of fresh and stained tissues and the fundamentals of histological technique are included. The study of the development is based largely on preparations from the chick, pig, and man. The anatomy of the central nervous system is given as an integral part of the course and comprises gross and microscopic studies of the human brain and spinal cord, with special emphasis on functional relationships.

This is an ideal general training on the subject, and many would decide that it is sufficiently special in its

FIG. 10.—ANTHONY N. BRADY MEMORIAL LABORATORY.



directions; but the student, confronted with his first direct medical study, can elect to follow that study along 31 different branches by special arrangement.

The subject of public health has similar opportunities for specialisation, though here the student, being in the second period of his studies, may be assumed to know better where his bent lies. The instruction in this subject in the Brady Memorial Laboratory runs thus: The first half of the course is designed to equip the physician for his function as a hygienic adviser to the family, dealing particularly with the environmental factors which affect health, such as the sanitary control of water, milk, and other foods, the disposal of wastes, and the control of communicable diseases. The second half deals with the organised community health programme and the relation of the physician to the work of official health administrative agencies, medical supervision of school-children, problems of industrial hygiene, and infant welfare and antituberculosis movements. But he can elect to follow up 19 subjects falling under the general heading of public health.

Similar opportunities for early specialisation occur throughout the curriculum and may be taken as a feature of the Yale course.

The Examinational System.

Students having acquired, and proved the acquisition of adequate knowledge of the sciences upon which clinical medicine is based, enter for a general qualifying examination to prove that they are able to correlate and utilise knowledge of the various medical and biological sciences as a basis for the study of disease. A student may present himself for this examination when, in his opinion, he is prepared for it. Students failing in this examination *may* be granted the privilege, after further preparation, of taking the examination a second time. A student who fails twice in the qualifying examination will not be allowed to continue in the school of medicine. Thereafter he must show his knowledge of clinical medicine and laboratory technique. Later on, examinations given by the Faculty of Clinical Medicine must be successfully passed and a satisfactory thesis written, while knowledge of their elective subjects has to be displayed.

HOSPITAL TRAINING.

Instruction in clinical medicine is given in two groups of courses. The first group, required of all students, is designed to provide opportunities for the student to acquire, in logical sequence, a sound knowledge of the principles involved in medicine and experience in the study of the natural history, diagnosis, and treatment of diseases. The student body is divided into sections for these courses, which include clinical clerkship in the hospital and attendance in the various services of the dispensary. The second group, elected by students in accordance with their interests and ability, provides opportunities for advanced work in the particular fields of clinical medicine—internal medicine, surgery, pediatrics, obstetrics and gynæcology, and psychiatry. These courses, which are repeated throughout the year, are largely practical in nature and limited to small groups of students. Instruction is further extended by clinics and conferences arranged to afford comprehensive reviews of knowledge.

The New Haven Hospital.—The clinical courses of the students are conducted in this hospital, which has 400 beds, but, like all its similars in the United States, is contemplating great enlargement. The institution comprises, in addition to an administration building and a recently opened private pavilion of 54 beds, a medical, surgical, and gynælogical block, a pediatric ward, and rooms devoted to treatment and diagnosis. The four services thus indicated are staffed by the faculty of the school. The medical service, in addition to 40 beds for the usual diseases, has 34 beds in a contagious pavilion. Surgery has available 109 beds, and gynæcology and obstetrics occupy 78 more. Sixty-one beds, of which 34 are in an isolation building, are devoted to pediatrics.

The *University Clinic* is alike used for instruction in the school and as a dispensary. Instruction is there given by the whole faculty in general surgery and medicine, and all the specialties, and while the laboratory facilities of the hospital are available to the clinic, there is also a laboratory for medicine and pediatrics in the grounds of the hospital, equipped for both routine work and research.

The *Brady Memorial Laboratory*, the gift of the family (Nicholas F. Brady B.A. 1899, and James C. Brady, B.A. 1904) of the late Anthony N. Brady, of Albany, N.Y., was completed and occupied in 1917. In 1928 an extension of this laboratory, together with two additional wings to be known as Lauder Hall and Farnam Memorial Building, was made possible through a gift from the General Education Board. These buildings are on the grounds of the New Haven Hospital and conform in architectural style with the administration building of the hospital. The Brady Laboratory and Lauder Hall serve as the centre for instruction in bacteriology, pathology, and public health. The former contains, in addition, an auditorium, a museum, and an autopsy suite. The serological work of the hospital is also done in Brady Laboratory, and the School of Nursing has classrooms and offices on the first floor. The Farnam Memorial Building adjoins Lauder Hall and is connected with the surgical and obstetrical wards of the New Haven Hospital. This building contains an auditorium, offices, classrooms, and laboratories for the divisions of surgery and of obstetrics and gynæcology. Treatment rooms in the basement and first floors for physical therapy, heliotherapy, cystoscopy, and accident cases, and an operating suite on the fourth floor, including rooms for operative obstetrics, provide additional facilities for the hospital.

VI.—THE MEDICAL SCHOOL OF THE UNIVERSITY OF PENNSYLVANIA.

Historical.

The School of Medicine of the University of Pennsylvania is the oldest in the United States. It was founded in 1765 by Dr. John Morgan, who became its first Professor of Medicine, and who prophesied its future strength in his opening address. Morgan was the pupil of John Hunter, and of William Cullen, of Edinburgh, and it was from Edinburgh that the new school derived its chief inspiration. For a period the headquarters were at various places in the city —among others, in the Presidential House built for George Washington—but in 1873 the school moved to a site adjoining the Philadelphia General Hospital, familiarly known as "Blockley." Then the University Hospital, the first hospital in the United States erected for the use of a medical school, was built, and since then the story has been one of continuous development. Various departments, suitably housed, have made their appearance, with appropriate laboratories, and a large quarter of the city has become a medical centre. The Robert Hare Laboratory of Chemistry, erected in 1877 and at one time the home of the Dental School, now houses the General Chemical Laboratories of the School of Medicine, the Laboratory of Physiological Chemistry, and, on the top floor, the dissecting-room. In 1892 the Laboratory of Hygiene was built, and in 1904 a building was erected to accommodate the Laboratories of Pathology, Physiology, and Pharmacology. The Robert Hare Laboratory will be shortly vacated, as a new building is under construction, attached to the present Laboratories of Pathology, Physiology, and Pharmacology, and this will house the Departments of Anatomy and Physiological Chemistry. The Wistar Institute of Anatomy and Biology, incorporated in 1892, was the first American university institute devoted to advanced study and research in anatomy and biology.

In 1894 the William Pepper Laboratory of Clinical Medicine was erected adjoining the University Hospital, and provides facilities for the prosecution of minute clinical studies and original researches. The Henry Phipps Institute for the study, treatment, and prevention of tuberculosis, was established in 1903; the building, located at Seventh and Lombard-streets, was completed in 1913, and organised and equipped for its university connexion.

In 1909 the University of Pennsylvania originated the first graduate courses in Public Health leading to a degree of Dr.P.H., the Laboratory of Hygiene being erected for the research work and teaching, while the Department was established in 1920. In 1910 the Department of Research Medicine was organised, and in 1916 a "merger" between the Medico-Chirurgical College of Philadelphia and the University of Pennsylvania was completed, and the Graduate School of the University was organised, while two years later the Philadelphia Polyclinic and College for Graduates in Medicine merged with the Graduate School to form a Polyclinic Section. The whole story, it will be seen, is one of the pooling of efforts, and along this policy the future of the Medical School of the University is being designed.

The Medical Curriculum.

Matriculation and Requirements for Admission.

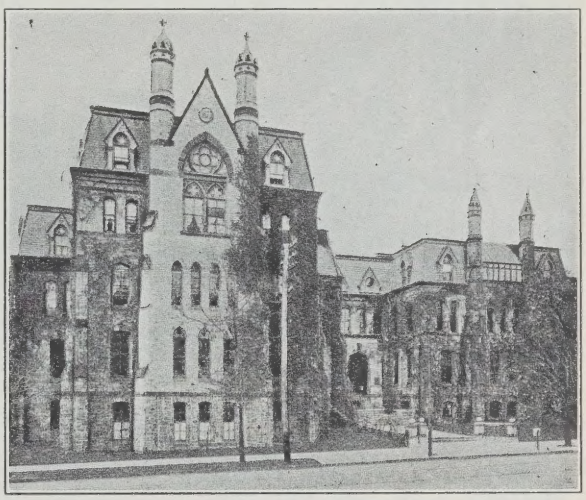
The minimum requirements are a standard four-year high school course or its equivalent, plus three years in an approved college of arts and science, aggregating not less than 45 units, a unit of college work being the same as a semester—namely, the equivalent of one hour of lecture or recitation each week for the full academic year or of two hours of laboratory work each week for the same period. The candidates must have the following credits or satisfactory certificates or proof of having passed an examination in these subjects: chemistry, physics, zoology or general biology, English, and either French or German. The credits should show that the applicant has done appropriate laboratory work in the three science subjects. Students can be admitted to advanced standing, that is to say, can enter in the second and third year classes, on proof that they have satisfactorily completed courses equivalent in kind and amount to those taken by the class to which admission is sought. Only 110 students are admitted yearly, though at least eight times that number make application.

Summary of Studies.

The course of medical instruction proper extends over a period of four years, and the subjects of the first two years follow upon each other in logical sequence.

First Year.—The time is devoted chiefly to anatomy, gross and detailed embryology, normal histology and neurology, physiology, and physiological chemistry.

Fig. 11.—University of Pennsylvania.



Administration Building.

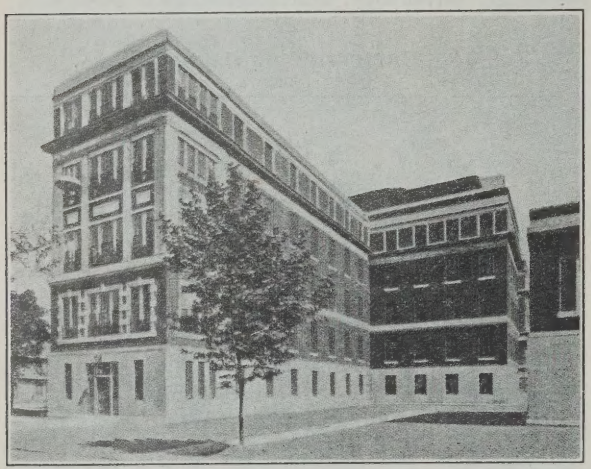
Students are taken in sections, and the instruction in physiology may be used as an example. It covers work on the circulation and respiration and on metabolism, while laboratory work on frogs and the turtle heart is amplified by experiments on the students themselves; so a gradual course is arranged from foundation to coping.

Second Year.—The subjects are pathology, bacteriology, and pharmacology, under which is implied all inquiry into practical therapeutics conducted by animal research. Instruction upon all the subjects of the first two years is almost entirely practical, so that the greater part of the student's time is spent in the laboratory; but a simultaneous introduction is made to clinical work, for once a week throughout the first and second years an elementary medical clinic is given, while a surgical clinic is given in the last half of the year to demonstrate to the students the proper relation of the fundamental sciences to the practical work of healing. Limitation of the first and second year classes to 110 students prevents the possibility of overcrowding the laboratories and ensures a large amount of individual instruction. The major part of instruction in pathology is concentrated in the latter two-thirds of the second year, courses correlating the teaching with ward work extending over the concluding years of the curriculum. In the second year, general and systemic pathology, including parasitology, is lectured upon and demonstrated by teachers,

care being taken to present aspects of the subjects not always contained in text-books and, as far as possible, connected with recent observation. The autopsies at the University and Philadelphia General Hospitals are attended regularly.

Third and Fourth Years.—With the beginning of the third year, detailed instruction in the three great clinical subjects, medicine, surgery, and obstetrics, and in the various specialties, occupies the student's time; and, just as there is no sharp dividing line between the work of the first and the work of the second year, so there is no sharp dividing line between that of the third and that of the fourth year. While the major part of instruction in pathology is concentrated in the latter two-thirds of the second year, in the third year clinico-pathologic conferences are held; patients presenting unusual points of interest

FIG. 12.—UNIVERSITY OF PENNSYLVANIA.



Completed block of new hospital.

are presented for debate by the staff, at which groups of students are present.

The main work of the students during these years is in the wards of the hospitals especially connected with the University—namely, the University Hospital, Philadelphia General Hospital (Blockley), and the Pennsylvania Hospital. The students are now separated into ward groups, and as the various teachers and their assistants are in the wards of one or other of these institutions practically all of each morning, the students are under supervision constantly, and advice is always at their disposal. In medicine they take histories of new cases which are allotted to them, and make physical examinations of each case as it is assigned to them, and they see any special treatment which is produced in the ward. Each student attends special departments of one of the out-patient departments, and in this way gets three months' experience, working there three to five hours a day. Lectures are given throughout the third year which assist the student in his systematic reading to accompany the more intensive clinical work in the fourth year. Each student of the fourth year class works in the clinical laboratory, making routine examinations of all material from patients assigned to him in any of the departments during his final year. At small clinics a case-history will be debated by the fellow students of the reporter, in the presence of the professor, who examines the class upon the diagnosis arrived at and gives reasons for his own views.

The course of instruction in surgery is distributed over two and a half years, for it starts in the second year with an introduction to clinical problems. The third year instruction deals with surface lesions and lesions of the extremities, and lesions of the cranial, thoracic, and abdominal cavities are considered in the fourth year. Every patient admitted to the wards is assigned to whoever takes the history, and the clinical clerk or dresser will follow the patient throughout his stay in the hospital, attending the operative clinics on the cases which have been assigned to him for history-taking. In the closing phase, the student, having mastered the principles of wound repair, anæsthesia, asepsis, antisepsis, hæmorrhage, and shock, attends special units of the out-patient departments, while he is required to make routine laboratory examinations. A course of operative surgery is given on the cadaver. During the fourth year the student, who has been trained in pelvic diagnosis and obstetric procedure on the manikin, attends ten labour cases at least, as well as lectures on gynæcology and conferences upon gynæcological cases recently admitted to the wards.

Examinations and Promotions.

The personal supervision that is possible by the teachers over small classes of students with whom their association is so close makes the processes of weeding-out and of advancement very thorough. The Dean is the last authority in all circumstances, and an interesting sidelight on his responsibilities is thrown, in this University, by the assumption that some of the students may be partly supporting themselves by paid work in what is called their "spare time." By periodical examination the students are placed in category, promoted or referred to their studies in accordance with their instructors' opinions, or rejected. The student who falls behind through stress of private circumstances cannot be categorised as either idle or dull, and wherever possible he is helped, so that the undue strain may be removed.

HOSPITAL TRAINING.

There are three hospitals in the city of Philadelphia at which the students may complete their curriculum—namely, the University Hospital, the Philadelphia General Hospital, and the Pennsylvania Hospital.

The Hospital of the University of Pennsylvania was founded in 1874 and now contains 540 beds. As is the invariable case in the large general hospitals at these great medical centres, the alterations of buildings and the rebuildings have been immense, and to-day both the general, and especially the surgical aspects, are represented in large and well-organised departments, while 22 internes are required to cover the growing demands, as well as six residents. The students, in accordance with the scheme of the curriculum described above, receive clinical instruction in small groups, while larger sections are taken by the professor or his associate over more general ground. The classification of patients treated in the two great medical and surgical departments shows that the training is fundamental, while the departments of gynæcology, pediatrics, ophthalmology, neurology, and orthopædics have adequate facilities. At the laboratories of clinical medicine and surgical pathology bench instruction is given, so that familiarity is obtained with the routine examinations and with the methods in which the numerous tests required by practice in the wards are carried out. There is a department of physiotherapy, and annexed to the hospital is the fine William Pepper Laboratory. Further developments are contemplated in view of new buildings, while the large out-patient department has been recently reorganised, and the dispensary service divided into a general diagnostic section, and a number of special clinics.

The Philadelphia General Hospital.—The hospital stands immediately adjacent to the University buildings, and can well be designated a hospital of the University, a large proportion of the students being always engaged in taking their clinical courses there. The ancestor of the hospital was the "Bettering House" or "Almshouse for Relief and Employment

of the Poor," which from 1767 to 1834 served the purposes of the English workhouse and its infirmary. This building was superseded by a general hospital and lunatic asylum, known for local reasons as "Blockley," and this in its turn has been largely replaced by the enormous modern hospital which is nearing completion. It has 2000 beds, and is constructed with complete thoroughness upon the most modern design. Clinical instruction to the students is indicated by the subjects with which they are to make themselves familiar during the third and fourth years of the curriculum.

FIG. 13.—UNIVERSITY HOSPITAL: THE SURGICAL PAVILION.

An example of a morning's work may be given. The visiting staff officer attended by an interne, the clinical clerk, to whom the duty of reporting the case has been assigned, and a small group of students who have reached the final stage of their course meets the professor, who is also a full physician or surgeon to the hospital. The clinical clerk reads his notes in the presence of the patient, who may, if necessary, be examined. The notes contain a history of the patient, the signs and symptoms on admission, and the results of the laboratory tests that may have been necessary. He is then asked for his diagnosis, when the rest of the class are invited to comment upon their contemporary's work and to suggest alternative diagnoses. All these speculations are then reviewed by the member of the staff who may, for example, rule out one theory as being obviously contradicted by the history, and a second view as being not supported by the symptoms, and so on, until the final diagnosis remains between two or three possibilities. The professor then indicates to the class the reason for his own selection, or he may say that to make any such selection is unsafe without further information. In particular the professor might ask for more assistance from the laboratory than his clinical clerk could supply. Finally, he indicates to the class what sort of information from observation in the wards or findings in the laboratory

he hopes to obtain, and recommends certain places in medical literature where his hearers can read trustworthy accounts of the condition in question. The small clinic thus described is typical of many similar procedures not only in other departments of this hospital, but throughout all the teaching hospitals in America. That this sort of training, more or less of it, is going on in all the centres described may be taken for granted.

The Pennsylvania Hospital.—This institution was founded in 1751, and to it the same story of progress may be applied. It has all the departments necessary for the student's curriculum, and especially a notable neuropsychiatric clinic.

The Episcopal Hospital, a general hospital with 450 beds, is also at the disposal of University teachers and students.

VII.—THE JEFFERSON MEDICAL COLLEGE.

THE Jefferson Medical College was organised in 1825 and in 1828 received a University Charter from the State making it an independent Corporation with the same status as the University of Pennsylvania. The College buildings consist of a medical hall, with lecture rooms, theatres, a museum, a library and laboratories, and special class rooms. On the uppermost, or sixth floor, in addition to the museum are an animal room and the research laboratory of the professor of preventive medicine and bacteriology. The library proper contains more than 6000 volumes, and another library, the Daniel Baugh Library, contains 1200 further volumes dealing with anatomy and embryology.

THE MEDICAL CURRICULUM.

Matriculation and Requirements for Admission.

Candidates must present evidence of having completed a four years' course at an approved high school and two years at an approved college of art or science, the evidence being held satisfactory by the usual semester and credit proofs. The two years at college must have been spent in acquiring ground work in inorganic and organic chemistry, physics (where it is urged that the course should be preceded by mathematical study including trigonometry), biology and English, the additional subjects recommended being a modern language, comparative vertebrate anatomy, psychology, and social science.

SUMMARY OF STUDIES.

The medical course of four years is so arranged that the student is being trained throughout in the fundamental and practical sides of his future calling.

First and Second Years.—The first two years are devoted mainly to the fundamental medical sciences, which serve as a basis for the technical and clinical studies that follow, the larger part of the time being spent in practical work in the laboratories. Emphasis is laid upon the laboratory instruction in anatomy, histology, embryology, physiological chemistry, physiology, hygiene, bacteriology, pathology, pharmacy and pharmacology. For laboratory instruction each class is divided into three groups, thereby affording greater opportunities for individual instruction. All courses are obligatory, and satisfactory work and attendance constitute a requirement for admission to the written examinations. As the ultimate object of the study of medicine is practice, the student, during the *Second Year*, is instructed in the fundamental principles of clinical medicine and surgery, in order that the correlation between theory and practice may be established in his mind early in the course.

Third and Fourth Years.—The laboratory courses are correlated with the clinical branches considered in the third year. During the fourth year the teaching is largely clinical and practical. The fourth-year class is divided into sub-groups of 10 or 12 men, who receive instruction at the bedside and in the dispensaries of the College Hospital and its departments, as well as in other hospitals. Didactic lectures and recitations are given in the Medical Hall on practice of medicine, physical diagnosis, surgery, obstetrics, gynæcology, materia medica, therapeutics, neurology, chemistry, physiology, pathology, bacteriology, medical jurisprudence, hygiene, pediatrics, genito-urinary diseases, orthopædic surgery, ophthalmology, and tropical medicine.

In the College and Laboratory Building, laboratory instruction is given in physiology and pharmacology, physiological chemistry, pharmacy, pathology, including morbid anatomy and pathologic histology, bacteriology, hæmatology, bandaging, major and minor surgery, obstetric manipulations, clinical chemistry, and microscopy. Courses in anatomy, applied anatomy, dissection, histology, embryology, and operative surgery are given also, while in the theatre there are clinics on general medicine, surgery, obstetrics and gynæcology, and all the special subjects. Hospital sections and small ward classes are taken to the bedside or to various special dispensaries, ward-teaching rooms, operating rooms, and mortuary.

The clinical side of obstetrics is taught in the Jefferson Maternity and its dispensary, and in the Wharton-street Dispensary, and regularly scheduled instruction is given in the Jefferson Hospital, Philadelphia General Hospital, the Pennsylvania Hospital, and the Philadelphia Hospital for Contagious Diseases.

Examinations and Promotions.

No student is admitted at any stage to examination unless his class record is satisfactory; students who fail to pass in not more than two subjects can be re-examined before the opening of the next session, and if successful will not lose precedence, but failure in both subjects again will mean removal. Failure in one subject will entail removal of this bad mark by successful examination during the next year, but a student may only carry one such condition into his third year's work, and no conditions are allowed in the fourth year.

HOSPITAL TRAINING.

The *Jefferson Medical College Hospital* is administered by the same board of trustees as the College, and the staff is composed of members of the Faculty and their assistants. By this arrangement all departments of College teaching, including every detail of clinical instruction and laboratory investigation, may be fully correlated. The present hospital was opened in 1907.

The ground floor is devoted exclusively to out-patient services, which also occupy the larger portion of the first floor, in which there are, in addition, administrative offices and reception rooms. The second, third, and fourth floors and part of the eighth, are devoted to ward patients, and, with the private wards, afford accommodation for 377 patients.

The out-patient department is a very large one, the hospital being situated in the centre of the city. The department is so arranged as to afford facilities for the examination and treatment of patients, in which every detail may be followed by students, assigned in sections to the various departments. Under qualified assistants detailed by the professors in charge, students are admitted to wards in which bedside instruction is given. Six operating rooms are especially equipped for section teaching. Under the supervision of professors and instructors, students are required to participate in operations and to assist in the administration of anæsthetics, and are in this way brought into direct contact with the most important details of operative procedures. When the interests of the patient are not thereby jeopardised, the student may follow the case from admission.

VIII.—THE MEDICAL SCHOOL OF JOHNS HOPKINS UNIVERSITY.

Historical.

THE School of Medicine was opened in 1893 as an integral part of the University and in close affiliation with the Johns Hopkins Hospital. The famous letter of Johns Hopkins, in which, exactly 20 years previously, he set out the reason and meaning of probably the largest and most liberal-minded piece of individual charity that has ever been exercised, contains the following paragraph addressed to those whom he selected as the trustees of the movement: "In all your arrangements in relation to this hospital you will bear constantly in mind that it is my wish and purpose that the institution [hospital] shall ultimately form a part of the medical school of that University, for which I have made ample provision by my will."

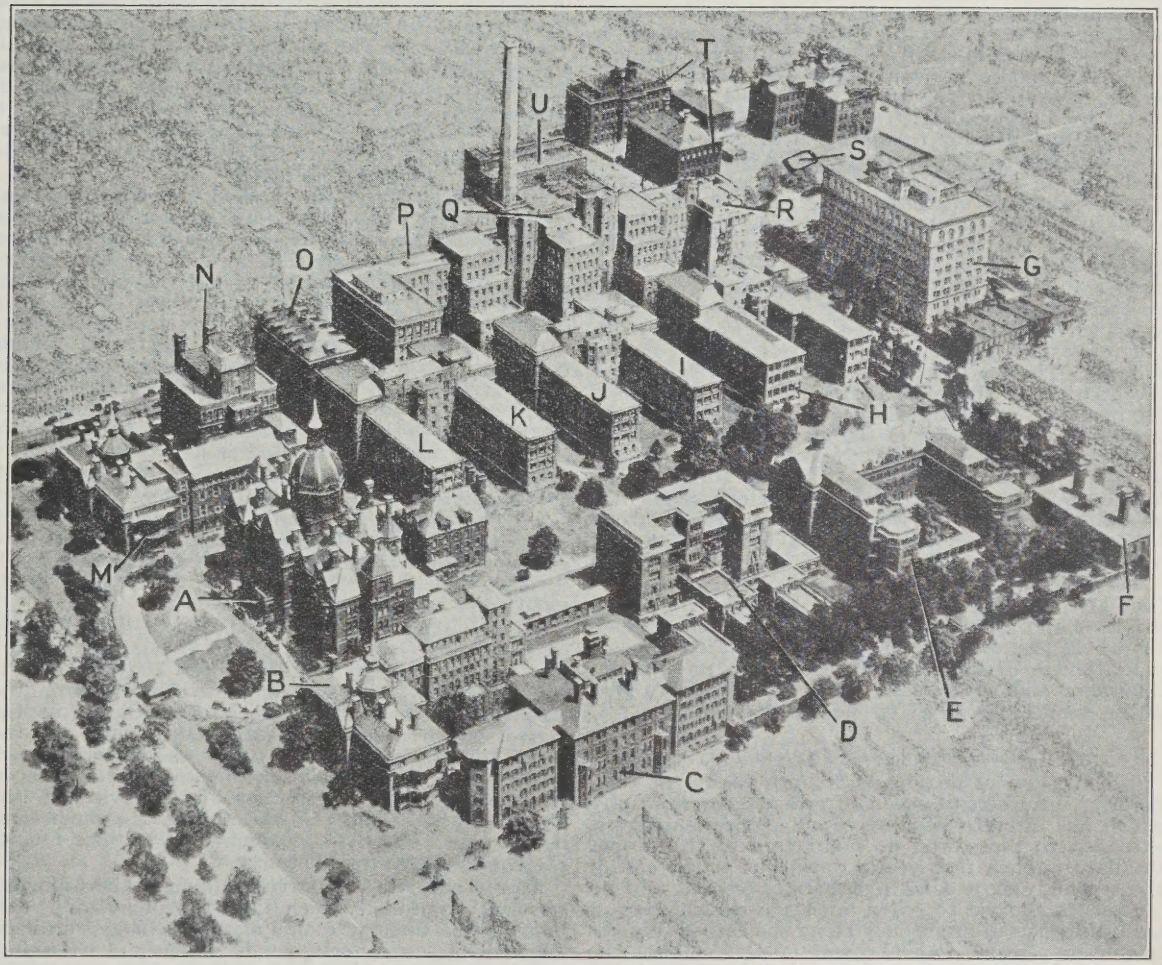
From the opening of the school all the instructors in the underlying scientific branches have devoted their entire time to University duties, while the establishment of the William H. Welch Fund for the advancement of clinical teaching by the General Education Board, some 20 years later, secured a similar basis for the responsible instructors in medicine and surgery and pediatrics. Further endowments have secured similar provision for psychiatry, obstetrics, and ophthalmology. The hospital, which was to be the clinical training ground of the school, was built in 1889; it then had 230 beds and it now has 750. The aerial view shows what it has developed into, and it need hardly be said that it is in the course of making large developments.

THE MEDICAL CURRICULUM.

Matriculation and Requirements for Admission.

The course of medical instruction extends over four years, and the number of students in each class is limited to 75, only students of real promise being admitted. The requirements for admission are a collegiate degree from an approved source, with certification that the applicant has satisfactorily completed certain minimal tests, those being: one year of college work in biology—comparative anatomy, embryology, or zoology being recognised; two years' work in chemistry—three years' work being advised, and inorganic and organic chemistry having been taken; one year of college work in physics; and a reading knowledge of French and German, with an elementary familiarity with Latin grammar.

FIG. 14.—AERIAL PLAN: JOHNS HOPKINS UNIVERSITY, BALTIMORE.



Key to Illustration of Johns Hopkins University.—A, Administration Building. B, Wilmer Ophthalmological Building. C, Old Nurses' Home. D, Harriet Lane Home (Pediatrics). E, Phipps Psychiatric Clinic. F, Laundry. G, School of Hygiene and Public Health. H, Woman's Clinic (Gynecology and Obstetrics). I, Wards. J, Wards. K, Wards. L, Wards. M, Marburg Building (General Surgery and Medicine, Private Pavilion). N, Kitchen Building. O, Brady Urological Clinic. P, Surgical Building. Q, Dispensary. R, Pathology. S, Site of Welsh Medical Library. T, Medical School. U, Power Plant.

The choice of students is made by taking into consideration the character of the college from which the applicant has graduated, his standing in the subjects, and the opinions given by his science teachers; where possible, a personal interview is obtained. As vacancies occur for any overt reason in the second and third years, students are admitted to advanced standing on proof that they have received the equivalent medical training and are able to pass the examinations of the class to which admission is sought.

Summary of Studies.

The major subjects for the four years of the course are: (1) anatomy (including histology and neurology; (2) physiology; (3) physiological chemistry; (4) pharmacology; (5) pathology (including bacteriology); (6) medicine (including physical diagnosis, neurology and clinical microscopy); (7) surgery; (8) obstetrics (including gynæcology); (9) psychiatry; (10) pediatrics; (11) ophthalmology.

In the present curriculum, as recently planned, the work of the *First Year* is so arranged that the student spends practically all of his time in required courses in anatomy (including histology and neuroanatomy), bacteriology, physiological chemistry, physiology, and pharmacology, with a fair proportion of free time in the last quarter of the year. In the *Second Year* the student is required to take courses in pathology, normal physical diagnosis, diagnostic methods, and clinical microscopy, so scheduled that the fourth quarter of the year is entirely free from any required work. In the *Third Year* instruction for the most part is in small groups, and only a minimal number of hours of instruction for the class as a whole have been set down. Required courses in obstetrics, gynæcology, ophthalmology, medical zoology, and hygiene occupy a small portion of the year, but the major part of the student's work is in medicine, in surgery, and in neurology-psychiatry. Courses in each of these three main divisions of medical instruction are given during each of the quarters of the year; the student may select the quarter in which he takes any of the subjects, thus having required work for three quarters and one quarter entirely free. In the *Fourth Year* a similar arrangement is made, but the student is required to take only one quarter's work in medicine and one in surgery. These two major courses are given each of the quarters of the year, and the student may select the quarter for each of the subjects, though, as in the third year, a limitation of the number of students to be accommodated in any of the courses is necessarily imposed. One-half of the student's time in the fourth year is thus entirely free for courses of his own choosing, for additional work in the required subjects, for investigation, or for migration to other medical institutions.

It will be observed that this is an extremely liberal type of curriculum and well calculated to train practitioners of medicine in the double direction which to-day is the model objective—namely, to become practitioners of medicine along modern methods of treatment and at the same time to take active part in the scientific progress of their profession.

Examinations and Promotion.

The method of dealing with unsuccessful or temporarily unsuccessful students differs here from any which has hitherto been observed. More leniency is extended to those who do not attain to the proper standard in their first year's work, but at the end of the second year a definite barrier is erected and no student is allowed to enter upon the clinical side of his training until proficiency along the earlier subjects has been proved. At the end of the courses the rejections are treated as individual cases, and the students are informed of the particular place in which they have failed to satisfy the requirements of the University, and are advised how to make good their deficiencies. If that cannot be done within a reasonable space of time the school is closed to them.

Hospital Training.

The clinical teaching in the hospital is to a large extent informal, and is conducted for the most part in small sections. During the second year the student is taught, in the hospital, the elements of medical and surgical diagnosis. He is introduced to the technique of history taking, of making a physical examination, and of examining the body fluids and excreta by chemical and microscopical methods. In this work he is also taught the use of the more common instruments for examination, such as ophthalmoscope and laryngoscope. This instruction is almost entirely practical, and makes use of the clinical material, and very little of the time is given to didactic lectures. Thus by the time the student enters the third year he has had an opportunity to become familiar with the technique of the basic examinations essential for diagnosis.

The clinical teaching in the third year in medicine, surgery, and neurology-psychiatry is conducted almost entirely in the out-patient department, although in the case of medicine ward patients are used to a limited extent. In the out-patient department the student participates in the daily routine of the clinic, taking histories and examining patients. In this work he is supervised by an instructor. Whole-class clinics in which diagnostic problems presented by patients seen that day in the clinic complete the morning's work. The afternoons are to a large extent free for elective work, although the students in medicine are required to divide their time between working in the clinical laboratory and examining selected cases on the wards. In the third year all the required work in obstetrics is completed. In addition to the section and whole-class exercises in this subject, each student is required to live for a week in the Women's Clinic, and thus has an opportunity to participate in all the activities on the delivery floor during that time.

In the fourth year the student serves as a clinical clerk on the medical wards and as a surgical dresser on the surgical wards for one quarter each. Upon him devolves the responsibility of taking the history and performing the simpler laboratory examinations of those cases assigned to him. Data obtained by him thus go to form part of the permanent case-records of the hospital. He attends ward rounds which are conducted with small groups as a rule, and has the opportunity to attend whole-class clinics. A few exercises in pediatrics and psychiatry complete the required work of this year. Half of the student's time is left free, to be utilised as he chooses.

The basic idea of the entire curriculum is to teach the fundamentals of the medical sciences in as short a time as possible, to train the student in the elementary technique of examination, and thereafter to give him abundant opportunity to educate himself by participation in the routine work of the departments and by independent study.

The appointments originate in the Medical Faculty of the University. After a man is nominated for a post on the Medical Faculty of the University he is recommended for a part of equivalent rank in the hospital. Thus the professor of medicine in the University becomes the physician-in-chief to the hospital, and upon him devolves the dual responsibility of the teaching in medicine and the care of all the patients and the medical service of the hospital, whether on the wards or in the out-patient department. Similar arrangements obtain for all the services and for all ranks.

The in-patients are divided amongst the following services: *medicine*, including neurology and dermatology; *surgery*, including gynæcology, urology, laryngology, and orthopædic surgery; *obstetrics; pediatrics; psychiatry; ophthalmology.* At the present time some of the subdepartments, notably urology, possess a relatively large number of beds at their disposal. This disproportionate growth is the result of fortuitous grants or bequests and does not represent a studied attempt to exalt the specialties.

The Johns Hopkins Hospital.—This is rather a congeries of hospitals than a single institution. The number of beds is something under 800, but extensive additions are already planned to the blocks of wards lettered I, J, K, L. The hospital contains 11 complete departments with all necessary laboratories. The dispensary deals with over 200,000 visits per annum, the applicants for assistance on the charity side representing some 25 per cent. of the total. Every form of general and special service is here represented.

The medical wards of the Johns Hopkins Hospital, as well as the laboratories for clinical instruction of students, were built almost 40 years ago, which makes them venerable structures in the United States. An entirely new medical clinic has been planned as a complete unit, containing wards, dispensary, laboratories for students, laboratories for routine work and for investigation, and rooms and small amphitheatres for teaching, and one portion of the structure has been completed, including out-patient accommodation, various groups of laboratories, and certain teaching rooms. The contemplated additions and modifications are large, and recent constructions show how huge the intended scale is. The dispensary or out-patient department of the medical clinic has been planned so as to divide the patients in a manner which would be analogous in many respects to the medical wards of the hospital. In such relatively small units it was believed that the most efficient service might be rendered to the patient and the most careful work done by the physicians. At a dispensary unit at the Johns Hopkins, therefore, the average number of patients seen varies from 25 to 40 a day; one physician and his assistants are in attendance. Eight students are received for instruction. Each unit is complete in itself and includes waiting space for patients, a consultation room for men, another for women, three examining rooms for men and three for women, a laboratory, a treatment room, a dark room for ophthalmoscopic and laryngoscopic examinations, a room for group teaching of students, a room for secretary, and one room for the nurse and social service worker. There are five such units, and one unit half the size of the others. Three of these are used for general medical cases, one is devoted to syphilis, and one to tuberculosis. The half unit is employed for the special study and treatment of particular groups of patients referred from the other units. It is used on different days for diabetic patients, for the treatment of patients with asthma and hay-fever, or for selected cases of cardiac disease. In addition to these units, which are strictly a part of the medical clinic, there is a unit for neurology and one for dermatology, both of which are nominally subdepartments of medicine. These units occupy four floors of the building, with certain waiting-rooms for fluoroscopic and anthropometric examinations, while the fifth floor is devoted to chemical and physiological laboratories and to offices for the staff. Chemical and physiological laboratories, a biological laboratory, a tuberculosis research laboratory, and a departmental library are also included.

Choosing internal medicine as the branch of study by which to illustrate the methods of instruction, the work is divided into an elementary course, a minor course, and a major course. Each course is approximately of eight weeks' duration. The number of students accepted in any one of these courses is limited. For the elementary course 75 students are accepted, for the minor course 25, and for the major course 20. The elementary course is offered once each year, the minor course three times a year, and the major course four times a year. Any student who has completed satisfactorily the elementary course or an equivalent may apply for admission to the minor course, and any student who has completed satisfactorily the minor course may apply for admission to the major course. This arrangement disregards entirely the fact that the student happens to be in the second, third, or fourth year of the medical school. It gives him the privilege of selecting the time in which he will do his required work in clinical medicine, and places on his shoulders very largely the responsibility for determining the sequence in which he will pursue his studies in the clinical subjects. It also makes it possible to accept special students for these courses in clinical medicine who may come from schools other than the Johns Hopkins, provided their training meets the necessary requirements for admission. The elementary course consists substantially of instruction and practice in the technique of physical examinations which the students must acquire before subjecting the sick to examination, and in history-taking. Later the student is trained in the examination of the blood, urine, and fæces, is instructed in the physical examination of abnormal conditions, and attends conferences and lectures on the interpretation of abnormal physical signs. During the minor course in medicine the student spends his mornings in practical work in the dispensary, attends at noon each day clinics in one or another clinical subject, and divides the afternoons between work in the wards and more advanced work in clinical microscopy.

The students in the major course are assigned to the medical wards as clinical clerks, where their principal object is to observe carefully the symptoms and signs of disease as an active process, and the reactions of human beings to the different disease processes. Each day there are clinics in various subjects, and a feature is made of case demonstrations in the wards. Lastly, the curriculum at Johns Hopkins University is devised to allow the student to follow elective work.

IX.—THE MEDICAL SCHOOL OF NORTHWESTERN UNIVERSITY.

Historical.

THE Northwestern University Medical School was organised as far back as 1859 as the medical department of the Lind University of Chicago, which has now been replaced or merged in the newer institution. This medical school was not only a pioneer in the advancement of medical education in the United States, but was one of the first schools organised in the country as a medical department of an existing university, while it was actually the first American school to enforce a standard of preliminary education. This led to the adoption of longer annual courses of instruction and, in the event, to a graded curriculum in which the studies were assigned in logical order with proper division and association between laboratories and clinical facilities. The medical faculty severed its connexion with Lind to become affiliated with the Northwestern University ten years later, becoming the medical department of that institution. From this time forward the location of the school, which was growing more and more important, changed for various reasons, and in 1905 it became an integral part of the Northwestern University on the Lake Shore Drive, the marine parade of the city, designed to spread indefinitely round the lake (Fig. 15). The magnificent building was given to the University in 1924 by Mrs. Elizabeth Ward in memory of her husband, the late Montgomery Ward.

THE MEDICAL CURRICULUM.

Matriculation and Requirements for Admission.

In addition to the usual certificates of good character, the requirements are as follows: the candidate must have completed two years of work in an approved college or university, following the completion of a high school course or its equivalent. The two years of college work, calculated as usual by semester hours, will have been employed in studies leading to

degrees in science or medicine, and during those two years the student must have acquired knowledge up to the requisite point, of chemistry, zoology, and physics; of English and of one foreign language, and of other subjects such as economics or history, certain variations in the curriculum being here allowed. That the principles of selection between candidates who can prove their suitability is freely exercised stands out from the figures. 130 new students are taken each year; most or all are already university graduates, and those who gain entrance hardly amount to 10 per cent. of the candidates.

SUMMARY OF STUDIES.

First Year.—The time in the first year is occupied with gross anatomy, histology, and embryology, and with chemistry, organic and inorganic, while the student is introduced to physiology, and receives a certain amount of training in psychology.

Second Year.—The main feature of the work in the second year is the large amount of time occupied in physiology and pathology, both subjects being, as might be supposed, chiefly pursued in the laboratories. A full course in bacteriology is taken in this year, while, together with pharmacology, come the courses in the physiology of digestion and metabolism. By lectures and by laboratory work the student learns the action of common chemical agents as well as the physiological implications of absorption, immunisation, anaphylaxis, and so on. In this year also the student is instructed in the art of physical diagnosis, and begins the study of neurology and psychiatry.

Third Year.—Just as the second year could be regarded as a continuation of, or a correlation with, the first year, so the third and fourth years are definitely linked up with the studies of the preceding period. The main instruction is now given in certain hospitals, and for this purpose the students are admitted to the Cook County Hospital, St. Luke's Hospital, and the Wesley Hospital which, when originally erected in 1901, was adjacent to the medical school. In the third year the student covers what may be called the whole ground of medical practice. In the lecture room, in special clinics, in the wards, or in the laboratories, his time is divided between medicine, surgery, obstetrics and gynæcology, with special stress laid upon neurology, genito-urinary surgery, and pediatrics. The necessary clinical pathology is studied, as well as such special departments as dermatology and oto-laryngology.

Fourth Year.—In the fourth year the medical curriculum is completed by the carrying forward of these studies, with the addition of ophthalmology, orthopædic surgery, medical jurisprudence, and active practice in a lying-in hospital — both in the wards and in the out-patient department. The student also must serve his time as clerk both in the hospital and dispensary. In the fourth year the students, who will by this time number about 120, are taken in groups of 40, and within these groups demonstrations are given by the different teachers to small classes of students, the instruction being given both in the third and fourth years. Groups of six men are assigned to one of the three hospitals for various periods for clinical clerk service, one-third of the class being assigned to the out-patient departments. Small groups of students are given instruction in cardiac pathology and physical therapy, while instruction in contagious diseases is met by the permission to certain students to spend one week of continuous residence in the municipal contagious hospital. In short, the work of the senior year is clinical in character.

FIG. 15.—MONTGOMERY WARD MEMORIAL: MEDICAL AND DENTAL SCHOOLS OF THE NORTHWESTERN UNIVERSITY.

Fifth Year.—A year's work as an interne is required for graduation. The class is divided into three divisions: clinical clerk service, out-patient service, hospital clinics and ward walks. Clinical clerks spend 11 weeks of the senior year in an assigned hospital on the wards and in contact with clinical cases. Each clinical clerk must report a minimum of 20 cases. Each case report will include the history, physical findings, symptomatology, clinical laboratory findings, diagnosis, prognosis, general progress, management, and a brief review of the literature. Senior students on out-patient service report cases from the out-patient department in the same manner as students on clinical clerkships. An outcall service is maintained with the out-patient department. Students on the hospital service may elect special clinics in

the several affiliated hospitals. "Ward walks" are a distinctive feature of this service, a phrase that recalls the fact that, until some 50 years ago, clinical education in Great Britain was always termed "walking the hospitals."

Examinations and Promotions.

The system has been very carefully thought out. At the registrar's office the reports upon the students during their course are received from their teachers, graded upon a system of percentage marks under the letters A to F. The lowest passing grade, C, requires an average throughout of 70 per cent., but though this is the minimum of marks for a pass it will not command promotion, an average of C being needed. If during a single quarter a student does not maintain an average of C, he is warned, and a warning in successive quarters constitutes a "probation." A student placed on probation must maintain for the period specified the average grade imposed by a committee on scholarship, and failure results in refusal of further registration. Below 60 per cent. of marks, indicated by D, earns "a condition" for the student, and a condition in one course earns a warning, and in two courses earns probation. Below 60 per cent. implies failure. A student who receives a failure in one course is automatically placed on probation, while if a condition is not removed before the end of the following quarter a failure is recorded, and this must be removed not later than the beginning of the next school year. Examination in any subject may be imposed by a committee of the school before promotion is granted.

Regular examinations are held at the end of each quarter. Second examinations are set for students who have been absent from regular examinations, or who have failed to receive a passing grade at a regular examination. Students delinquent in two or more branches after re-examination are required to take those branches a second time and may not elect studies that conflict with them. Further re-examination may be obtained by special permission.

HOSPITAL TRAINING.

The students receive their principal training at the Cook County Hospital, St. Luke's Hospital, the Wesley and Lying-in Hospitals, though the resources of other institutions are drawn upon.

The Cook County Hospital.—This institution includes a general hospital, a tuberculosis hospital, children's contagious diseases and psychopathic hospitals, with appropriate dispensaries and pathological department. The number of beds in the Cook Hospital is for the moment about 3600, but enlargement is in course of construction, and the pending alterations affect to some extent the bed capacity of the main structure. The psychopathic hospital has 167 beds, and its duty is to act as a diagnostic clinic, so that the length of residence in this hospital does not average more than six days. The Cook County Hospital provides clinical treatment in its various wards for the medical students also of the universities of Chicago and Illinois. The accompanying plan, drawn from the air, shows the general lay-out.

The hospital requires 15 internes, and over 700 autopsies are performed yearly. These, together with weekly clinico-pathological internes, permit groups of students, duly supervised, to get a close insight into the methods and meaning of diagnosis, while in the general pathological laboratory, the biochemical, the electrocardiac, and basometabolic laboratories, they become acquainted with the developments of modern research. Instruction in all the specialties is given both in large general clinics and to small sections of students, especially in the out-patient department.

Wesley Memorial Hospital is situated in the vicinity, and clinics in medicine and surgery are held here regularly and are attended by junior and senior students. The wards and private rooms contain together 225 beds. The operative clinics are a feature here. The hospital was opened in 1888 "for the gratuitous treatment of the medical and surgical diseases of the sick poor," and, largely owing to the munificence of the Deering family, is a fine example of medical charity.

St. Luke's Hospital.—This hospital contains upwards of 400 beds, of which more than one-quarter accommodate free patients. It is for the reception only of acute curable non-contagious diseases and injuries, and the financial status of free or part-pay patients is investigated. The opportunities afforded are freely used by the students principally in their fourth year, and operative clinics are conducted daily.

The Chicago Lying-in Hospital, in the most thickly populated district of Chicago, has 140 beds. It cares for poor women also in their homes. Every student assists at three or more operations, and resides in rotation during three weeks when he is required to attend six or more deliveries, and to make from 80 to 120 post-partum visits.

The Michael Reese Hospital, having, with the *Sarah Morris Children's Hospital* some 400 beds, is regularly attended by senior students for instruction in pediatrics.

X.—THE MEDICAL SCHOOLS OF THE UNIVERSITY OF CHICAGO.

IN the University of Chicago, founded by the late J. D. Rockefeller, we meet with a pattern of education that is definitely founded upon the intention to regard medicine as a branch of university learning, not to be differentiated, save in its particular bearings, from any university faculty; the training, consequently, is designed to be upon lines analogous with those laid down in other departments of the University. The medical curriculum proper is of five years duration, the fifth year being the period of internship.

The medical schools of the University include: (1) the Graduate School of Medicine of the Ogden Graduate School of Science; (2) the Rush Medical College; and (3) the Rush Post-Graduate School of Medicine, whose activities are without the scope of these notes.

The following is an announcement of the University and indicates the objectives of the authorities:—

The Graduate School of Medicine of the Ogden Graduate School of Science was organised in 1924. Its purpose is to serve the medical sciences by research and teaching. It is a part of the Ogden Graduate School of Science and its work is done on the University quadrangles in close contact with that of other scientific departments—physics, chemistry, biology, &c. Departments devoted to the pre-clinical sciences were provided for when the University was founded and established shortly thereafter. Their primary purposes are the development of the sciences and the training of scientists. Since 1899 they have included among the courses offered all those required in the first two years of work leading to the degree of Doctor of Medicine as well as those leading to the degrees of Bachelor of Science, Master of Science, and Doctor of Philosophy. With the definite organisation of the Medical School there have been added on the quadrangles clinics and departments devoted to the clinical medical sciences, similarly related to the Ogden Graduate School of Science and with the same general character and purpose. The work of these departments leads to the degrees of Doctor of Medicine, Master of Science, and Doctor of Philosophy. Candidates for the degree of Doctor of Medicine do the work of the first two years in the Graduate School of Medicine in the Ogden Graduate School of Science on the quadrangles of the University.

The work of the third and fourth years may be done either in the Graduate School on the quadrangles

or in Rush Medical College. The requirements for the fifth year may be satisfied either by a year of advanced work in some branch of medical science acceptable to the Faculty of the Graduate School of Medicine, or by a year of successful internship in an approved hospital.

Admission to the Medical Course.

The first- and second-year classes are limited to 100 in each class; the third and fourth-year classes in Rush Medical College are each limited to 140 men. Selection from among the applicants is made on a basis of qualities judged desirable in the pursuit of medicine other than scholarship. Every student must show evidence of satisfactory vaccination.

A Bachelor's degree, equivalent or approximately equivalent to that conferred by leading colleges and universities, is required for admission, and the college work must have included certain semester hours of work in the natural and physical sciences. The applicant must have a reading knowledge of one modern language other than English (German or French preferred); this knowledge is tested by an examination, largely scientific in character. Evidence of interest and ability in research will help applicants.

Certain medical courses are noted for attention, particularly physiological chemistry, quantitative chemical analysis and organic chemistry, embryology, comparative anatomy of vertebrates, pathogenic bacteriology, general bacteriology, and physiology; but it is noted that the study and practice of medicine is so wide a field that no college training can fail to find possible usefulness. The use of the English language, psychology, physical chemistry, advanced biology, advanced mathematics, history, economics, sociology, Latin, Greek, drawing are here suggested. The compulsory subjects are, as they almost must be, chemistry, physics, and biology, but students may prove that they have already studied a medical subject while at college, though this will not shorten for them the medical course proper.

The Ogden School.

Although the pattern is individual—so much so that an authority of the University may be found saying that there is no medical curriculum—the story of student education is similar to that told elsewhere; for pure science must precede applied science, and applied science must precede therapeutics.

In the Ogden Graduate School of Science the student's work may result in his obtaining the degrees of M.D., or D.Sc., or D.Ph. in accordance with varying conditions. The M.D. is awarded on the recommendation of either the Ogden Graduate School or the Medical Faculty of Rush College. The medical degree can be obtained without any collusion with Rush College.

The student, being of age, and having completed satisfactorily four years' medical work in a school approved by the University of Chicago, a certain proportion of which must have been done in the Ogden School, can obtain a four-year certificate, entitling him to serve as an interne for a fifth year and graduate in due course. He must satisfy the authorities of his adequate proficiency in anatomy, physiology, physiological chemistry, and pharmacology; in hygiene, bacteriology, and pathology; in medicine (including therapeutics, pediatrics, dermatology, and neurology); surgery (including orthopædics, ophthalmology, and otolaryngology); in obstetrics and gynæcology.

He must also satisfy *special* requirements of at least one department, and here he may obtain graduation on a Ph.D. thesis as fulfilment of the thesis requirement. He must have passed successfully final examinations in various groups of these subjects, and the examinations may be taken at any time when offered, and no individual course is specifically required for the M.D. degree.

Rush Medical College.

Historical.

At Rush Medical College the clinical medical sciences are acquired by the student in the third and fourth years of his curriculum. This College received a charter by a special act of the State of Illinois in February, 1837. Its founder Daniel Brainerd was its first president. The first course of lectures was delivered in the second story of a frame building on Clark-street, near Randolph, in 1843. In 1844 a college building was erected at the corner of Dearborn-avenue and Indiana-street (now Grand-avenue). In 1867 a larger building was erected on the site of the old one. This edifice was destroyed in the great fire of 1871, and for three years the College occupied a temporary amphitheatre on the ground of the Cook County Hospital, then located elsewhere. In 1875 a clinical building was erected, and in 1893 a laboratory building was erected hard by. The Senn Building, adjoining the clinical building on the east, was erected in 1903. In 1887 the College became the medical department of Lake Forest University, retaining, however, its autonomy. This relation was dissolved by mutual consent in April, 1898, and in the same month affiliation with the University of Chicago was established. In 1883 the Presbyterian Hospital, adjoining the College, was established in affiliation with Rush Medical College. In 1908 an affiliation was entered into with the Children's Memorial Hospital similar to that obtaining with the Presbyterian Hospital. This was transferred in 1919 to the University of Chicago. In 1911 a similar affiliation was entered into with the Home for Destitute Crippled Children, and in 1915 with the Country Home for Convalescent Children.

In May, 1924, a new contract was executed between the Corporation of Rush Medical College and the University of Chicago in accordance with which the affiliation of 1898 was superseded and the University took over the work of Rush Medical College as a department of the University.

Summary of Studies.

The candidate's work before proceeding to clinical studies must have his previous two years' activities duly accredited. That is to say, he must produce time and efficiency certificates with regard to his work in all the usual medical sciences—i.e., anatomy, histology, and embryology; physiology, physiological chemistry, and pharmacology; bacteriology up to a point and the pathology of the laboratory.

The work of the third and fourth years consists mainly of study of the clinical medical sciences: pathology, medicine (including materia medica, therapeutics, and medical jurisprudence), pediatrics, surgery, obstetrics and gynæcology, laryngology and otology, ophthalmology, and dermatology.

Optional courses in addition to those required above are offered to students who desire them, and they are encouraged to spend additional time in special work involving original investigation.

The laboratories at the disposal of the student are numerous, both large and small. The Kent Chemical Laboratory and the Ryerson Physical Laboratory are used for special research; the title of the Hull Biological Laboratories tells their purpose; while new laboratories of physiology, physiological chemistry, and pharmacology have been erected within the last two years. At Rush Medical College the Rawson Clinical Laboratory is placed in a building which houses also a pathological department and a free dispensary, while Senn Hall, erected through the munificence of the late Prof. Senn and other members of the medical faculty, includes a large out-patient department, where much clinical teaching is carried on, conference rooms, and surgical and medical amphitheatres.

Hospital facilities are to some extent in the making as a new hospital and dispensary to be an integral

part of the University structure are imminent. The present University Hospital has 208 beds (Fig. 22, and p. xxxix); the Presbyterian Hospital with 430 beds adjoins Rush Medical College. The students of Chicago University have also access to the wards of the Cook County Hospital and the Chicago Lying-in Hospital.

XI.—THE MEDICAL COLLEGE OF THE UNIVERSITY OF ILLINOIS.

Historical.

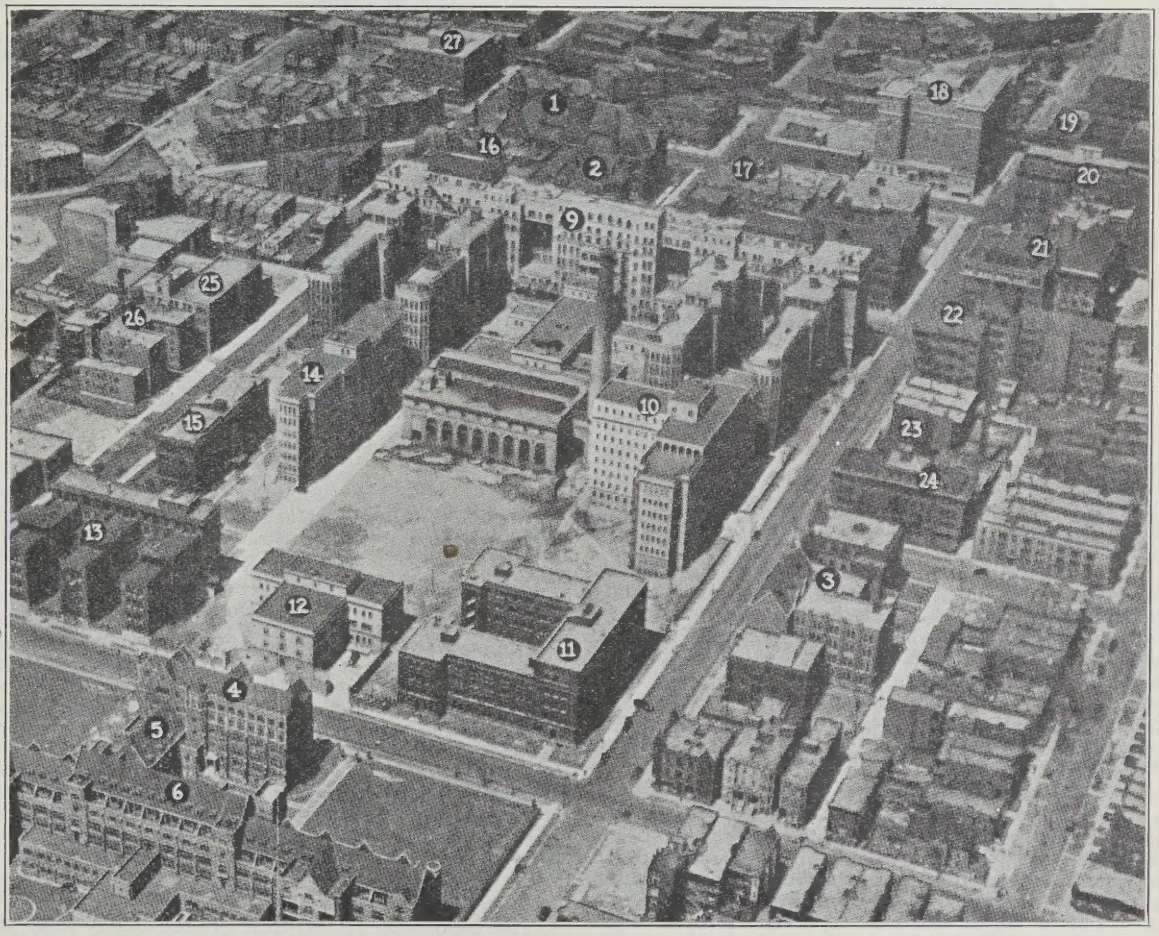
THE Medical College of the University of Illinois, including dental and pharmaceutical students, is situated in Chicago, the main University being at Urbana, 130 miles away. The personnel of this large faculty amounts to about 1200 out of a total of some 14,000 students. This College represents the development of what was 50 years ago the College of Physicians and Surgeons of Chicago. This College has been entirely absorbed, but its original buildings remain (though doomed to pass away) as the official block of the school. The medical school, like the rest of the University, is subsidised by the State of Illinois, the modulus accruing to the Medical College being some $400,000.00. The school, which is structurally in a condition of acute development, possesses a hospital of its own of 150 beds, for special purposes of teaching and for research, all the cases being of a charitable nature; while ordinary clinical instruction is provided for the students, as for the three other universities in the City, in the Cook County Hospital, St. Luke's, Augustana, and Michael Reese hospitals.

THE MEDICAL CURRICULUM.

Matriculation and Requirements for Admission.

For admission to the College of Medicine of the University candidates must present as a minimum four years of accredited high school work, or the equivalent, and two years work in a recognised college or university; the two years of university work comprising as usual the subjects of chemistry, physics, bacteriology, English, and German or French, while certain subjects can be taken voluntarily, such as an ancient language or more advanced mathematics or economics. The

FIG. 16.—THE MEDICAL CENTRE, CHICAGO.



The Medical Centre, Chicago.—The aerial plan shows the Cook County Hospital, where the students of the Chicago and Illinois Universities receive their clinical training, and all the associated institutions, except that for psychiatry and pediatrics, which are situated adjacent to the Main Hospital Building of State Research (see 6 on plan).

University of Illinois.—1, College of Medicine. 2, College of Dentistry. 3, College of Pharmacy. 4, Research Laboratory. 5, Library. 6, Main Hospital Building of State Research and Educational Hospital.

Cook County Hospital.—9, General. 10, Children's. 11, Psychopathic. 12, Morgue. 13, Tuberculosis. 14, Men's. 15. Contagious. 16, West Side Hospital. 17, Illinois Training School for Nurses. 18, Y.M.C.A. (West Side Professional Schools Department). 19, Presbyterian Hospital School for Nurses. 20, Presbyterian Hospital. 21, Rush Medical School. 22, Chicago College of Dentistry. 23, Memorial Institute for Infectious Diseases. 24, Durand Hospital. 25, Loyola Medical College. 26, Frances Willard Hospital. 27, University Hospital.

registered students in the medical curriculum thus have at least a seven-year course, consisting of two years of pre-medical work at Urbana, two years pre-clinical work in the College of Medicine in Chicago, two years of clinical work at one or several of the hospitals, and a further year as an interne in an institution approved by the University. It must always be remembered that the University of Illinois subserves the purposes of the State of Illinois, and some difference is made in respect to the admission of students from without, from whom there is required a scholastic average of at least 10 per cent. above the minimum passing grade.

Summary of Studies.

First Year.—In the first year of the medical course proper the necessary subjects are histology and microscopic anatomy, embryology, regional and systemic anatomy, and gross and microscopic anatomy of the nervous system. A commencement is made also in physiology, bacteriology, and physiological chemistry.

Second Year.—In this year a large amount of time is devoted to physiology and pathology; also to pharmacology, under which heading is included not only materia medica, but general therapeutics, toxicology, physics, and chemistry of the digestive, respiratory, circulatory, and nervous systems. The student is introduced to internal medicine, obstetrics, hygiene, and the fundamental principles of surgery, with instruction, for example, in asepsis, anæsthesia, and surgical dressing, and physical diagnosis.

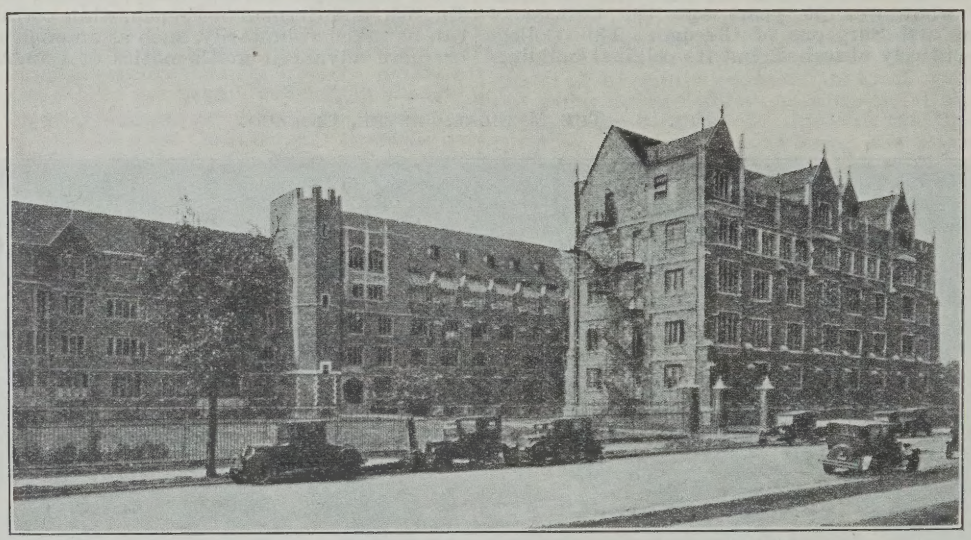
Third Year.—The greater part of the time of the student in the third year is naturally taken up by instruction in the art and science of general surgery and general internal medicine, in the wards of the hospital. Anatomy now becomes topographical, attendance at autopsy is required, instruction in obstetrics is continued, while special attention is paid to such specialties as dermatology, pediatrics, genito-urinary; orthopædic surgery, oto-laryngology, hygiene and jurisprudence also figure in the time-chart, and the length of hours in this year is considerably increased.

Fourth Year.—In the fourth year, while, as before, the greater part of the time is taken up by ward instruction in general medicine and surgery, the other subjects are pursued with various intensity, while the student is invited to take up a large portion of his time in what is termed electives. In other words, he is allowed to indicate the particular subjects to which he proposes to devote special attention.

The clinical instruction, while pursued for particular reasons at different smaller institutions, is largely carried on at the Research and Educational Hospital of the University, at the Cook County Hospital, St. Luke's, Augustana, and Michael Reese hospitals, institutions which provide between them a total of some 5000 beds.

For practical purposes the students admitted all come from the State of Illinois, and the first-year entrance is limited to 130 of those who have satisfactorily fulfilled the necessary tests, other approved students being placed upon a waiting-list. Selection is, no doubt, assisted by the culture of the applicant as indicated in his elective subjects for entrance.

Fig. 17.—University of Illinois.



Research Building, with Educational Hospital in background.

Following the procedure which has already been commented upon in connexion with other universities, a weeding-out takes place, so that at the end of the second year only some 90 to 100 students of the original selection remain, but owing to a liberal though well-scrutinised admission of students of advanced standing, the third year number requiring clinical training is again elevated to 125. These students are divided into groups for teaching purposes and receive instruction on the accepted pattern. That is to say, cases are allotted to them as clinical clerks. Their powers of history-taking, observation, physical diagnosis, laboratory findings, and diagnosis are tested by the professor or associated professor in the subject, and by fellow-students of comparable standing. They defend their judgment as best they can and the teacher uses the situation to give clinical instruction. The same process goes on in the dispensary.

Examinations and Promotions.

The candidate for medical graduation obtains the degree of Bachelor of Science in Medicine by reaching a required grade in three-quarters of the subjects of the curriculum, while of his four years' course one at least must be spent in the University. For the M.D. he must in addition complete a course of 12 months' duration in a hospital affiliated with or approved by the University, though in certain cases a year of research work will be accepted in substitution. Graduation with honours is regulated by the average

success obtained throughout the course, but as early as the second year the student may elect, with the approval of the head of the appropriate department, to pursue a definite line of endeavour, and his success here will count towards his honour degree.

Examinations are held periodically, and a system of marking regulates the procedure for failure. Students who have failed in major subjects undergo re-examination later, or may make good elsewhere if they produce the proof of having done so. Failures in minor subjects can be wiped out by special examinations held immediately preceding the next College term. Further, special examinations are held by arrangement with the Dean and the heads of departments, success at which will improve the candidate's grade in subjects where already average marks had been obtained. The student who fails badly may be required to withdraw, but the arrangements for readmission are fair and well thought out.

Hospital Training.

This takes place principally in the Cook County, the Michael Reese, the St. Luke's, and Augustana hospitals, of which institutions the first three have already been noted (see p. xxv), and, of course, at the Research and Educational Hospital of the University. The Augustana hospital is a general hospital of about 220 beds.

The Research and Educational Hospital.—In association with the Department of Public Welfare of the State of Illinois a group of hospitals and laboratories has recently been opened, affording the University adequate facilities for teaching and investigation. The buildings occupy a campus approximately eight acres in extent, located immediately adjacent to the Cook County Hospital. The units now in operation include the following: out-patient dispensary, general hospital, research laboratory and library, pediatric ward, and the orthopædic and psychiatric divisions. The hospital has been designed to afford comfort for the patient, and the use of the clinical material. At the present time some 200 beds are occupied, but a total of 450 is contemplated for the main building (Fig. 17).

The *first* floor of the hospital proper contains the pediatric, the obstetrical, and the rontgenological departments. The *second* floor of the hospital, in addition to wards, contains the clinical laboratories, with divisions for bacteriology, serology, pathology, biochemistry, and metabolism. The *third* floor comprises eight suites of operating rooms and their necessary service rooms, with special operating rooms for head and genito-urinary work. The *fourth* and *fifth* floors contain living rooms for internes and residents and the quarters for the managing officer of the institution.

An out-patient dispensary occupies the main floor of the hospital building. It possesses large waiting-rooms, suites for all divisions of clinical work, a large amphitheatre, drug dispensary, and preparation rooms (used in conjunction with the School of Pharmacy), electrocardiographic and hydrotherapeutic units being located in the basement of the building. In addition the administrative and service offices are located on this floor. Joining the hospital by corridors leading from the basement and the third floor the University has erected a laboratory building for the science group of the medical school. Here the basement houses the photographic and plastic divisions of the illustration studios. The Department of Pharmacology occupies the first floor, Department of Bacteriology and Pathology the second floor, and the third is used by the Department of Physiology and Physiological Chemistry. The Department of Anatomy occupies the major part of the fourth floor, and the entire fifth floor is given over to the Animal Hospital, Animal Surgery, and kennels for dogs and smaller animals.

We may take the Department of Internal Medicine by which to illustrate the student's course. The work in this department, although begun in the second year, is of course mainly done in the third and fourth years. In the second year, however, the whole class of 130 is divided into small groups, so that instruction is individual, and coincident with this course the student works at laboratory diagnosis. Thus he is ready for practical clinical work in the out-patient department in the third year, when in addition to attending lectures he has the opportunity to be present at conferences and clinics. Special emphasis is now laid upon clinical work, small groups at bedside clinics being given to not more than eight students simultaneously brings about close relations between him and the instructor on the one hand and the patient on the other. Physical diagnosis will be mainly inculcated in the second year, while the work in the third year will be done in the various wards and along selected lines in the Cook County Hospital and in the Research Hospital of the University. In the fourth year, while this clinical instruction is being generally carried to a higher point, in addition to a review course of principles, optional courses in the regional medicine of the heart and chest, in diseases of the blood and blood chemistry, and in clinical parasitology are provided.

Particular emphasis is placed upon the work of the fifth year. Students are distributed among various hospitals of the country, which have been recognised by the Council on Medical Education of the American Medical Association. This work is not done directly under the supervision of the Faculty, though at several hospitals where the majority of our students take the intern year, many of our professors serve on the staff. Written reports are received monthly from reliable persons in the various hospitals concerning the progress of the work of the students. By this system the county hospitals become interested in medical education, also the students feel that during this period they are still, at least to some degree, within the influence of the University.

XII.—THE MEDICAL SCHOOL OF THE UNIVERSITY OF MICHIGAN: ANN ARBOR.

Historical.

In the University of Michigan the medical school was the first school to be established, the actual organisation being planned in 1837, and the school opened in 1850. The University may therefore be said to have developed round the school and hospital, while the latter was represented 60 years ago by a transformed dwelling-house, containing 20 beds, provided to meet the needs of a small rural community. The romantic name Ann Arbor is derived from the fact that in the immediate vicinity of this early hospital there once stood an arbor in which two ladies, each named Ann, wives of local land-owners, were wont to entertain their friends while their husbands were among the early founders of the city.

The medical curriculum expanded together with the hospital accommodation, and what had been merely a course of lectures became a scheme of education under which, first, a year's clinical experience with a practitioner was demanded, and then, in rapid succession, compliance was necessary to a curriculum of two, three, and four years. This curriculum since 1890 has undergone the development entailed by the progress of medical science, resulting in sequence and concentration in the subjects presented, abundant laboratory teaching, and frequent survey in lectures and clinics of all that is taught.

The Medical Curriculum.

Matriculation and Requirements for Admission.

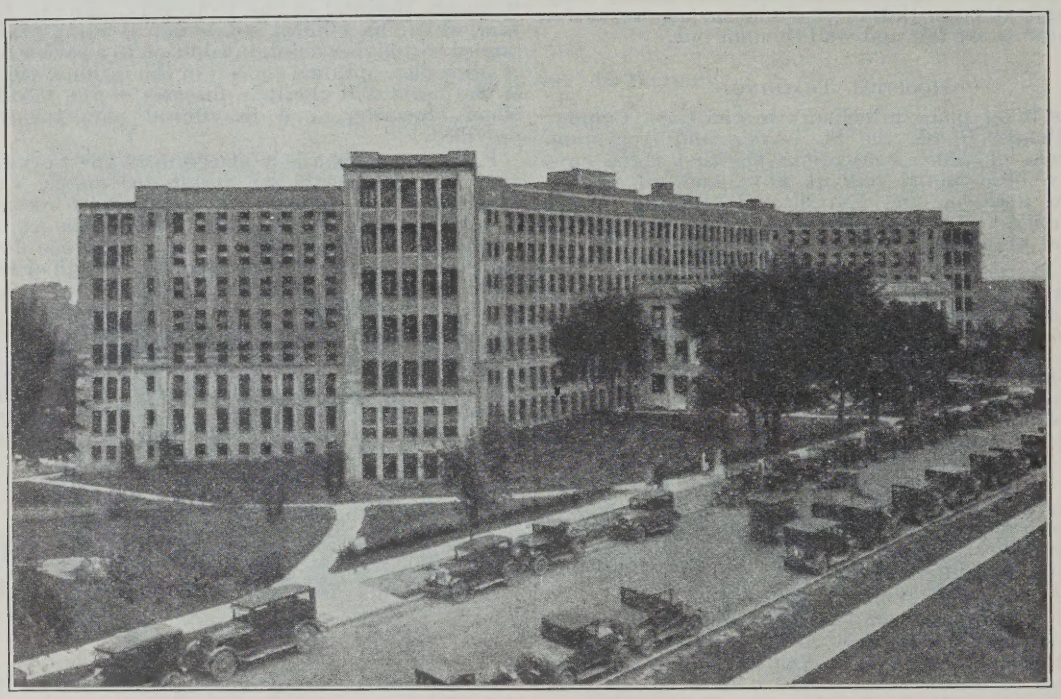
The applicant for admission to the medical school must present evidence that he has completed at least two years' work, calculated in semester hours,

in a recognised college or university, following upon a course at an approved high school. In the high school course Latin is a compulsory subject, while the pre-medical study in the University comprises, together with chemistry, physics and biology, instruction in English literature and composition, and familiarity with either French or German acquired by two years' study. A State board of registration in Michigan requies the submission to it of the credentials relating to the pre-medical study. Students may be enrolled on desiring to take a degree both in art and medicine, when a combined though rather longer course will lead to the double graduation.

chemistry, hygiene, bacteriology and pharmacology, and in the clinical laboratories. The same objective method of teaching is carried into the clinical work. During the first year the greater part of the day is spent in the laboratory; during the remaining years the mornings are devoted mainly to lectures and recitations, and the afternoons to laboratory drills, the study of methods of diagnosis, and means of treatment and clinical work.

First Year.—The subjects are, primarily, histology, embryology, and anatomy, developed into the anatomy of the nervous system and regional anatomy. Later

FIG. 18.—THE UNIVERSITY HOSPITAL, ANN ARBOR.



The number of students applying for admission at Ann Arbor is very high; as many as 1000 may apply, although it is not possible to admit more than a fraction of that number in a given year. In the course of the four years of the medical course proper the number dwindles through the falling away from the standard, but the care taken in selecting the students from among the mass of applicants is indicated in the fact that, whereas such casualties formerly amounted to as many as 15 per cent., to-day the figure is only 8 per cent. Every applicant is seen personally by the Dean, and no differentiation is made between the sexes.

SUMMARY OF STUDIES.

The clinical work is done at the University Hospital and the pre-clinical at the school, where the pre-clinical departments occupy three buildings, one of which provides ample accommodation for the study of anatomy, physiology, and bacteriology; another houses the laboratories of pathology, physiological chemistry, and hygiene; while the third is given up to pharmacology and animal research.

The medical curriculum covers four college years of nine months each. The first two years are devoted to the more strictly scientific work, which serves as a basis for the technical and clinical studies which follow. Stress is laid on laboratory instruction in anatomy, histology, embryology, physiology, physiological

in the year the subjects are physiology and physiological chemistry and bacteriology, all the subjects being presented in lectures, but worked at in the dissecting rooms and laboratory.

Second Year.—In the second year, in which the same subjects are taken up, there is a definite shaping of studies toward medical application. Anatomy is taught from the functional and surgical sides, time is given to clinical microscopy and physiological chemistry, and the study of drugs is commenced, the connexion with animal experimentation being displayed. Thus the student approaches pathology, while he is also helped to appreciate his approaching work in the wards by courses in physical diagnosis.

Third Year.—In the third year the practice of medicine in the wards and out-patient department is in full swing, the clinical work being done in the hospital of the University. Alongside of this training in the principles of surgery, medicine, and obstetrics, instruction is given by lectures and clinics in preventive medicine and in various specialties, such as pediatrics, ophthalmology, psychiatry, and neurology, oto-laryngology, and neural pathology.

Fourth Year.—The work is a development of that of the preceding year, but regular attendance at autopsies is required. The class is divided into sections, according as the particular study is in medi-

cine and surgery generally, in obstetrics and gynæcology, psychiatry and neurology, dermatology, pediatrics, ophthalmology, and oto-laryngology, a system of rotation securing a complete range of studies for all.

The course outlined leads to medical graduation, but at Ann Arbor there are combined curricula in science and medicine (B.S., M.D.), in literature and medicine (A.B., M.D.), and in pharmacy and medicine (B.S. (Pharm.), M.D.); for these combinations there are special regulations.

Examinations and Promotions.

Examinations are held in all subjects at set times. Students may be reported as having passed the course with a grade of A = Excellent, B = Good, C = Passed; or they may be marked D = Conditioned, E = Not Passed, and F = Incomplete or Absent. Students receiving a D grade are allowed one supplemental examination to remove the condition. Failure to remove the condition results in the course being reported "Not Passed." Subjects reported as "Not Passed" (E) must be taken over before the student is eligible to another examination in the same course. Courses reported as "Incomplete" or "Conditioned" (D), and not cleared within one year, become "Not Passed." During the first and second years in the medical school any student receiving two or more conditions or "not passes" in any one semester, and failing to justify the failure, will be removed from registration. During the third and fourth years the same rule applies, except that three or more "not passes" are allowed.

Lastly, no student can graduate until all his required work is complete, his conditions removed, and his examinations passed, but re-examination is allowed on fair terms and for satisfactory reasons. The curriculum is closed by a comprehensive examination which acts as a sort of sieve through which only the approved material can pass, while a fifth year is added to the course for the State licence, the time being spent as an interne.

HOSPITAL TRAINING.

The University Hospital has over 1100 beds; the hospital is owned by the University of the State, and it is understood that in consideration of their treatment the patients will be the subjects for clinical instruction. The teaching of medical students is announced in the official publication regarding the hospital as the primary object of this institution.

The hospital is placed on high ground overlooking the Huron Valley, and the main building, which has only recently been opened, offers every modern advantage of plan and equipment. The general plan, that of a double connected Y, on six storeys, provides for light wards and clinical laboratories in profusion; the first floor level is given over to a diagnostic department, where the various members of the medical staff have their examining rooms with teaching facilities supplied, and where the dispensary is placed. This out-patient department is a large one, for though Ann Arbor is a small town, it is in the immediate vicinity of Detroit—an immense and growing place. Patients are admitted to the diagnostic unit, and then from one medical service to another, until a complete diagnosis is made by the staff working as a group. A rear wing of the building houses the department of clinical pathology, the X ray rooms, and operating theatres, while a front wing is occupied by the administration.

A State Psychopathic Hospital is in close vicinity, as are buildings for tuberculous and infectious patients, and a convalescent hospital. In all these institutions, as in the main buildings, the clinical education of the student is carried on, with small rotating classes, by means of bedside instruction and conference.

MEDICAL EDUCATION IN CANADA.

I.—THE MEDICAL SCHOOL OF McGILL UNIVERSITY.

Historical.

UNDER the will of James McGill the Royal Institution for the Advancement of Learning came into existence 110 years ago, and three years later a Royal Charter was granted to the institution for the founding of McGill College, while the corner-stone of the Montreal General Hospital was laid. The interconnexion between the academic teaching of the university and the clinical teaching of the hospital was recognised from the beginning; and exactly 97 years ago the Montreal Medical Institution, that being the medical school of the hospital, was engrafted upon the new McGill University as its medical faculty. Throughout the following century during which the science and practice of medicine, as we now know them, have grown up, the Faculty of Medicine in McGill University has been a progressive and distinguished one and its graduates have been found among the advanced scientific thinkers and workers of the day.

THE MEDICAL CURRICULUM.

Matriculation and Requirements for Admission.

The medical graduate is required to take a seven years' course, two of these being pre-medical and five being directly concerned with his professional training. The candidate for admission to the first year of the curriculum must therefore prove that he has already completed two full years in some college or institution for the study of arts and science satisfactory to the University authorities, during which period he will have obtained instruction in physics, biology, and chemistry, while at the same time stress is laid upon the necessity for adequate knowledge of the humanities. Wisely, however, the authorities at McGill allow themselves a certain amount of latitude in the interpretation of their own statutes, so that they are not compelled to reject an obviously suitable candidate because in one of these subjects he may be weak. Proved accomplishment in other directions is allowed to counter-balance the temporary defect which in these promising students has always disappeared during the first month or two of professional training. That the high standard thus enjoined before admission to the first year of the faculty is fully justified at McGill is proved by the fact that over 80 per cent. of these intending adherents are already university graduates, while probably less than 20 per cent. of the applicants obtain admission. The graduates and admitted students come virtually from all parts of the world.

SUMMARY OF STUDIES.

The first year is occupied with anatomy, histology, bacteriology, physiology, and biochemistry. The next period, one of two years, is devoted to general pathology, such subjects as pharmacology and medical jurisprudence being also included. The final two years are occupied with the clinical application of this professional training—namely, in medicine, surgery, obstetrics, gynæcology, and preventive medicine. In order to qualify for the examinations at the end of each of these divisions the candidate must, of course, prove his diligence in the usual manner; he must pass in the subjects included in the first division before he can begin the work of his seventh term (that is the work in the third division); and he must pass his examination in the second division before he can proceed to the work of his tenth term, that is to say, the hospital study of medicine and surgery. In the closing examination

the subject of public health can be taken separately, but the examinations in medicine, surgery, and obstetrics must all be passed at one time, subject to certain leniency at the discretion of the medical faculty.

Examinations and Promotion.

Class examinations, oral or written, are held during the session to test the progress of the student. If the standing obtained by any student in these examinations is unsatisfactory, he is not permitted to take the *Final and University Examinations*. These are the ultimate test in determining a student's fitness for promotion or graduation, and cover the following subjects arranged in three divisions :—

First : (1) anatomy, (2) histology, (3) bacteriology, (4) physiology, and (5) biochemistry.

Secondly : (6) pharmacology, and (7) pathology and medical jurisprudence.

Thirdly : (8) public health and preventive medicine, (9) obstetrics and gynæcology, (10) surgery (including urology and orthopædic surgery), and (11) medicine (including pediatrics, neurology, psychiatry, dermatology, and laboratory diagnosis).

A student who has failed in the *Final Examinations* in any subject may apply for re-examination at the next examination period, and at the conclusion of each course he is graded in one of five groups : A (honours), B (good), C (fair), D (doubtful), and E (failure). The grade assigned to a student is based upon the tests but the record of the work done throughout the courses is taken into account and the quality of the English used by the candidate helps in determining his standing always. The rules for promotion following these tests have been summarised already, but in respect of the third or last division of the University examinations it should be noted that to qualify here in medicine, surgery, and obstetrics a candidate must have : (*a*) Attended courses extending over a period of not less than 15 terms. (*b*) Satisfactorily completed the prescribed courses of study and practice in : (1) ophthalmology, (2) oto-laryngology, (3) abnormal psychology and psychiatry, (4) infectious diseases, (5) anæsthesia, and (6) post-mortem examinations.

As has been said above, the completing tests in medicine, surgery, and obstetrics must all be passed at one time, but a student who fails in one of these subjects only may, at the discretion of the faculty, be allowed a re-examination in that subject at the next regular examination period, provided that he shall have satisfactorily completed such additional work as may be prescribed by the head of the department concerned. But the faculty reserves the right to require the withdrawal of any student at any time if, in the opinion of his instructors, he is incompetent. a promotion committee considering the cases of all students who at the conclusion of their third term are reported by their instructors as having fallen below the grade of C, in order to determine whether such students are to be allowed to continue, warned, required to repeat the course or courses, or retired from the school.

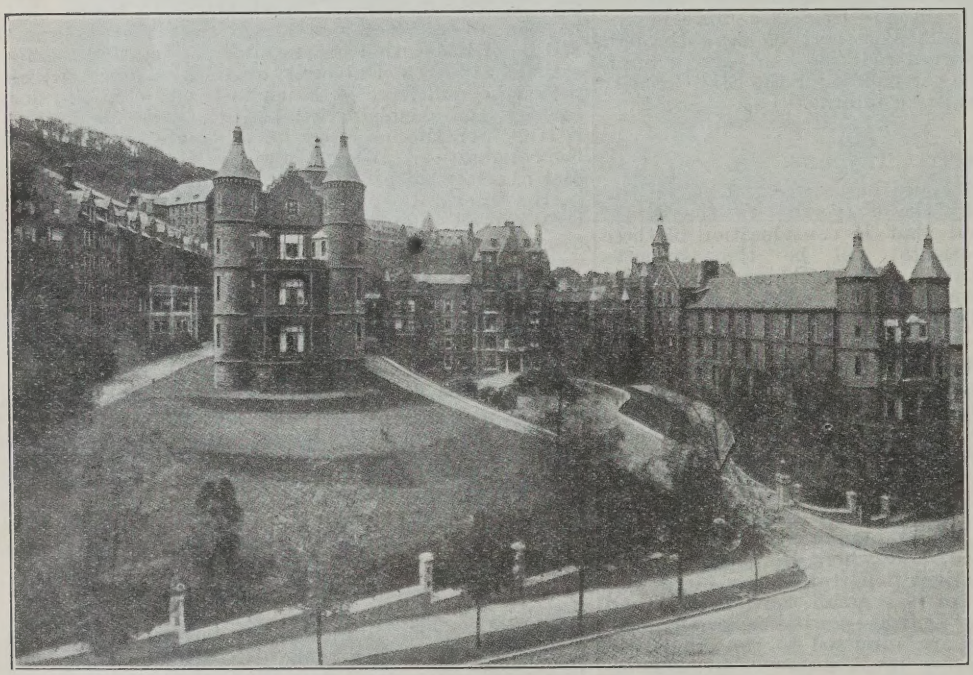
HOSPITAL TRAINING.

During the last two years the professional training is pursued in the wards mainly of the two great hospitals of Montreal, the Royal Victoria Hospital, and the Montreal General (Central Division). These two hospitals are institutions of which any city in the Empire might well be proud.

ROYAL VICTORIA HOSPITAL, MONTREAL.

The Royal Victoria Hospital of Montreal stands on a site of extraordinary beauty, and fits into its grand environment both in style and design of building, while remaining a model of practical efficiency—the beauty is there but no possible feature of utility has been sacrificed to the picturesque. The hospital is now 35 years old and owes its origin to two great and generous Canadian statesmen, Lord Strathcona and Lord Mount-Stephen, who decided jointly to build and equip an institution worthy of the future needs and importance of Montreal. This ambition was realised within one year of the project being decided upon, and in 1894 the Royal Victoria Hospital opened with 250 beds. It has now 700 beds, and the history is one of steady progression, of addition to the buildings and extension of the activities. Within 12 years the increasing demands upon the hospital's accommodation made it necessary to erect a fitting nurses' residence, while the original nurses' quarters were transformed into wards or laboratories. As with each year the pressure on the hospitals' capacity increased, new constructions were designed in keeping with the original building, and in 1916 the Ross Memorial Pavilion, containing six floors with accommodation for 120 patients, was added. This block was erected and equipped through the bounty of Mr. J. K. L. Ross, one of the hospital's governors, and is dedicated to the memory of his parents. The pavilion possesses its own operating suite, X ray, cardiograph, and physiotherapy departments. Upon its equipment no pains, either practical or æsthetic, have been spared, while in its kitchens all the cooking

FIG. 19.—ROYAL VICTORIA HOSPITAL, MONTREAL : MAIN BUILDING.



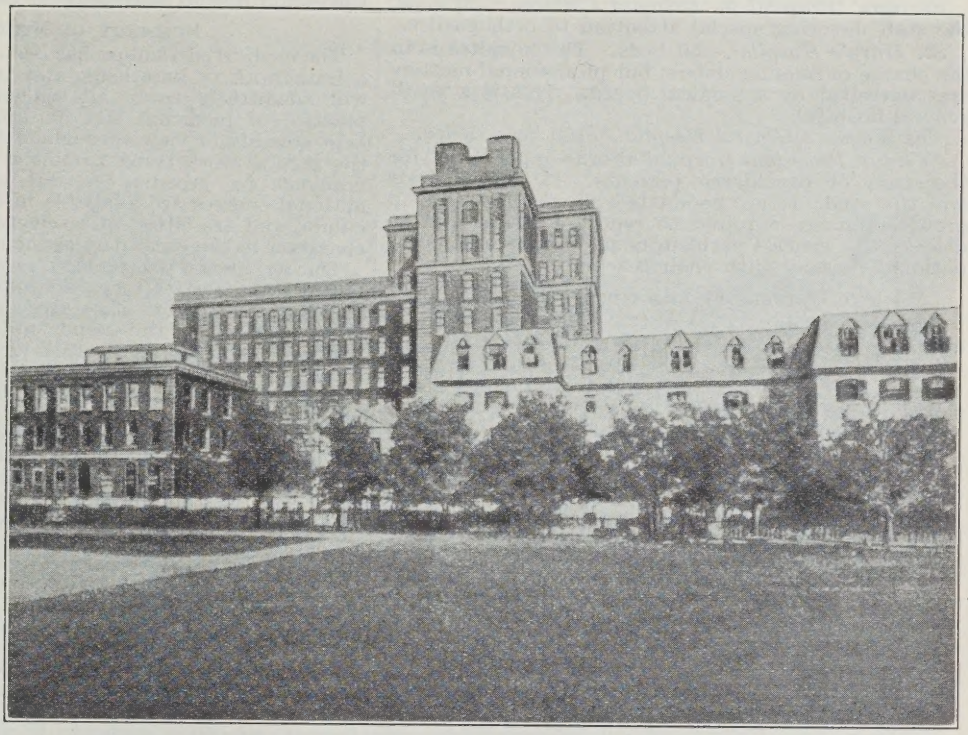
is done by the nurses as part of their training. The pavilion was opened 12 years ago by the Duke and Duchess of Connaught. In 1925 the hospital assumed control of the Montreal Maternity Hospital, which meant an addition of 75 beds to the central institution, and implied a very wise recognition of the prime importance not only to the community but to the medical students of a thorough training in obstetrics and gynæcology. The construction and equipment of this building were conceived after an inspection, undertaken by the officers of the institution, of the latest and best in similar hospitals in Europe and the United States, and the new building, which stands in the grounds of the main buildings, was opened in 1926 by Lord and Lady Byng. It constitutes a complete unit of nine floors, contains its own kitchens, stalls, operating-rooms, X ray department, and other necessary annexes. The two topmost floors provide accommodation for the nurses, and the patients' beds now number 212.

Montreal General Hospital.

The Montreal General Hospital is the senior institution, as may be shown by the fact that in 1927 it published its 106th annual report. It was founded rather as a dispensary with an infirmary attached, but a picture of the original buildings shows that by 1848 it had definitely assumed the character of a small general hospital. As a brief way of describing the progress of the institution this picture tells the story. The right hand lower portion is the original building as it was built in 1848 with certain structural alterations, while to the left stand the old medical buildings, and behind the great pathological building erected some ten years ago. Fronting the hospital is now an imposing building, completed two years ago as a residence and school for nurses, but like the Royal Victoria Hospital, Montreal General Hospital intends to progress, and judging by the plans for the future the progression implies the disappearance of the 1848 building and the completion of the pathological block by the addition of a central administrative department and of an entirely new wing to the right of the central erection. It is clear from the last annual report of the general superintendent that further extensions are contemplated, as forcible reference is made to the shortage of hospital beds felt from day to day in the city of Montreal.

The Western Division of the Montreal General Hospital, known as the Western General Hospital, is used for the treatment of acute diseases. It has 62 public beds and the post-mortem and surgical material is now being used for teaching, in which direction additional opportunities are contemplated.

FIG. 20.—MONTREAL GENERAL HOSPITAL.



The Hospitals of the Montreal Hospital Council.

While most of the clinical education of the medical students of McGill University is conducted at these two great hospitals, the Montreal Hospital Council, an association of the hospitals of the city of Montreal has under its superintendence 17 other hospitals, general or special in character, varying in bed capacity, and varying also in form of organisation. The following is the full list, and at those marked with an asterisk the medical students, in the closing stages of the curriculum, may obtain instruction.

**Alexandra Hospital.*—175 beds for the reception of contagious diseases. The students here receive instruction in the diagnosis and treatment of exanthemata.

Catherine Booth Mothers' Hospital.—50 beds. Under the charge of the Salvation Army.

**Children's Memorial Hospital.*—130 beds, with a large out-patient attendance. Primarily designed for the orthopædic cases, it now admits all varieties of patients giving the student a broad conception of pediatrics.

Homœopathic Hospital of Montreal.—50 beds.

Hôpital Français.—150 beds. General University. Semi-open.

Hôpital du Sacre-Cœur.—1500 beds. Care of incurables and of tuberculous patients.

**Hôpital Saint-Jean-de-Dieu.*—This hospital with 3300 beds is affiliated to the University of Montreal and provides a complete course of training with a special course of psychiatry. The institution has a contract with the Government of Quebec for the care of insane patients.

Hôpital Ste. Justine.—This is a private hospital with 165 beds, although it is designed to double its capacity. It is entirely a private corporation.

Hôtel-Dieu de St. Joseph de Montreal.—300 beds. General hospital.

La Misericorde Hospital.—This large hospital contains 600 beds, and although the services are of a general capacity, it is mainly devoted to the study of obstetrics and pediatrics.

L'Hôpital Notre Dame.—300 beds. Provides general services.

Montreal Children's Hospital.—Contains 50 beds, but an extension under which four times as many patients will be accommodated is under contemplation. The outdoor clinic here is exceptionally large.

**Montreal Foundling and Baby Hospital* has a capacity of 80 beds, and is designed to take care of sick and destitute children for the first two years of life. A large amount of clinical material is here provided, special consideration is given to the problem of infant feeding. Connected with the institution is a largely attended baby welfare clinic.

Shriners' Hospital for Crippled Children.—50 beds, the staff devoting special attention to orthopædics.

St. Mary's Hospital.—50 beds. The hospital is in the charge of nursing sisters, but professional matters are controlled by a medical board. This is a small general hospital.

The Women's General Hospital.—150 beds (help).

**Verdun Protestant Hospital* affords opportunity for the study of psychiatric patients. It has 630 beds and the students are conducted about the wards in groups, and are required to report on cases and to discuss the general problem of psychiatry and occupational therapy with their teachers.

The University and the Hospitals.

The association between the University and the affiliated hospitals is very close; indeed, it may be called complete, the university professors and teachers comprising the staffs of the hospitals, while in the election to those staffs the University has a predominant vote. The trustees of the hospitals, in the interest of donors and subscribers, as well as the province and city, have voices in the elections, but for practical purposes the University controls the issue. The Royal Victoria Hospital is adjacent to the medical school, and is completely equipped, as a general hospital, with all special departments; with the Montreal General Hospital the total of public beds provided for clinical study is some 700, while the beds in the affiliated institutions bring the full total up to about 2000.

II.—THE MEDICAL SCHOOL OF THE UNIVERSITY OF TORONTO.

Historical.

The University of Toronto dates from 1827, while the absorption of Trinity College, which had formerly possessed a medical faculty, dates from 1903. The medical faculty in its present form, and as an integral part of the University, dates from 1887; and, while the magnificent buildings that have now been erected in Queen's Park typify the growth and expansion of the University, they may also be taken to represent the progressive importance of the medical faculty.

The Medical Curriculum.

Matriculation and Requirements on Admission.

The Faculty of Medicine in the University of Toronto provides for a six years' course, but here the division varies from that at McGill, where there are two pre-medical and five professional, by having one year for honour matriculation, one year for pre-medical, and five years professional. The candidates for admission to the first year in the Faculty of Medicine must present pass matriculation certificates from the Department of Education of the Province of Ontario, showing proficiency in Latin, English, history, mathematics, a language, and experimental science, that is physics and chemistry; honour matriculation implies a choice of Latin, Greek, or a modern language, and one of the sciences. The faculty reserve a good deal of liberty in the substitution of subjects, the intention being merely to make sure that in addition to a knowledge of physics and chemistry up to a pass standard, the general education of the candidate is high enough to enable him to appreciate instruction in the immediate professional subjects. Candidates from the British Isles are admitted on the certificate of registration as a medical student with the General Medical Council of Great Britain, while those who possess a degree in arts from any recognised university also enter without question. Here, as at McGill University, although there is a generous appeal to other than local students, only a few non-residents can be accepted out of some 400 annual applicants, as those from the Province of Ontario are given preference in making up the entering class of about 120 students. There is reasonable flexibility in obtaining an equivalent standing by communicating to the Registrar of the University official statements of previous work.

Summary of Studies.

The medical curriculum has been designed to furnish a framework of knowledge and technical skill which will adequately equip all students for the general practice of medicine and its branches, and this is kept steadily in view throughout the whole six years, the regular work being amplified with special studies designed to broaden general education. Hence optional courses are available in the six years' curriculum, and are either of a scientific or a "cultural" character in the early part of the course.

During the *first year* biology, physics, and chemistry; during the *second year*, anatomy and physiology, histology and embryology precede the studies of the *third year* where the same subjects are developed, the anatomy of the central nervous system being especially studied, while bacteriology and elementary pathology and biochemistry are taken. The importance of the latter is recognised by three lectures a week throughout the year, laboratory courses in the Michaelmas and Easter term, and tutorial assistance one hour weekly, reviewing and supplementing the main work of the laboratory. At the end of each of these three years there is an examination, and the student cannot proceed to the study of the subjects in the following year until he has been successful in the preceding one, but there are supplemental courses to meet the case of "referred" candidates—that is to say, that a student failing, say, in one of the first-year subjects can use his long vacation by taking a supplemental course which will enable him if successful to pass on to the second year.

The *fourth year* is a critical one. The study of pathology is undertaken in academic manner, while clinical work in the wards in medicine and surgery commences. The student now receives a general introduction to pathology as applicable both to medicine and surgery, while he becomes familiar with the process of taking histories, and is instructed in the recognition of physical signs. This, therefore, is a very important year in the course, for if the student fails badly he may have several subjects in which he is required to make good in the supplementary classes. This may result in the loss of a year's study, while there is a system by which persistent failures may make continuance of the curriculum impossible. These considerations hold good in the case of the unsuccessful student also in the two last years.

In the *fifth year* the hospital instruction is in full fling, and while there is a marked difference between the procedure in the two clinical years of the British schools and those of Toronto University, the result will come out much the same. The student does not "dress" or "clerk" for a particular member of the staff, but for periods of ten weeks he receives clinical instruction from different teachers, while what is termed "theatre teaching" proceeds in clinics, and the classes are divided into small groups for clinical instruction in the wards. Bedside clinics on different types of diseases are given weekly, while the students are engaged in taking histories, examining patients, and carrying out the clinical laboratory investigation of their patients, and a weekly clinic is held in the hospital amphitheatre, at which cases are present illustrating different types of diseases. In addition to medicine, surgery, obstetrics, and therapeutics generally the specialties of pediatrics, hygiene, toxicology,

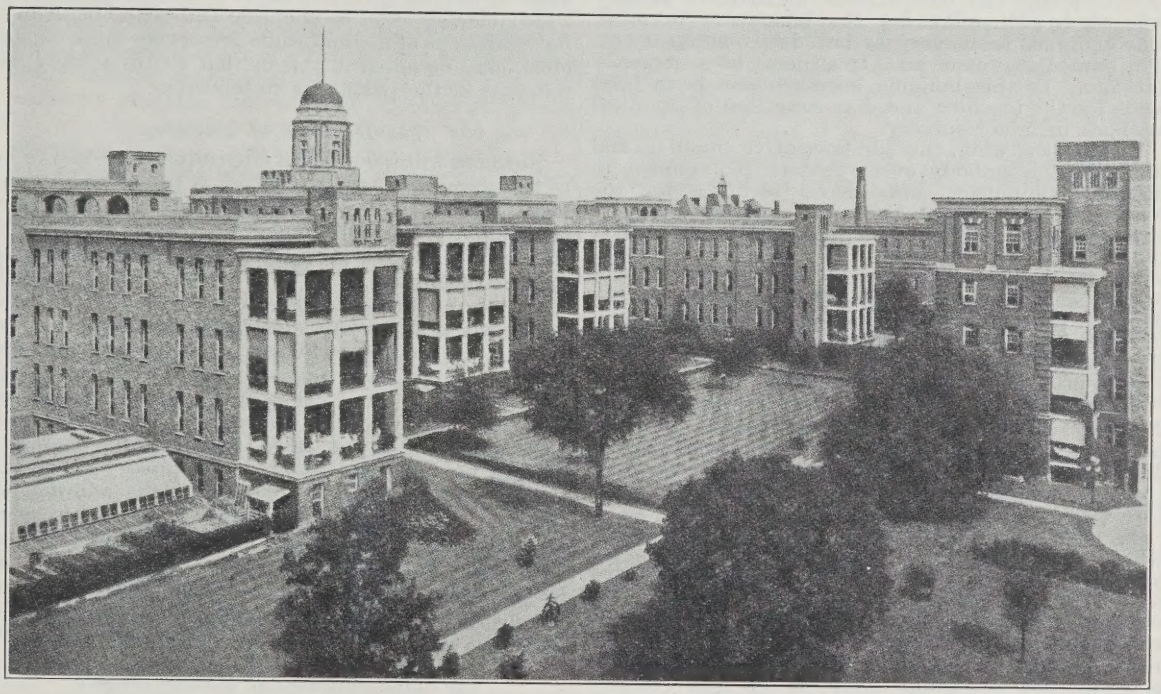
and pathological chemistry are introduced, and attendance is required at 12 autopsies. Students who have completed the work of the fifth year are also required, before commencing the studies of the sixth year, to undertake field work in public health and preventive medicine.

In the *sixth* or final year the students are placed in three groups—medicine, surgery, and specialties—and the time is divided thus: For a period of ten weeks each group devotes its whole time to clinical medicine with a similar period to clinical surgery; for five weeks to obstetrics and gynæcology; five weeks to special subjects. In this year the students have patients in the ward allotted to them, and the staff in this department, including balance, polarimeter, combustion, and experimental rooms. Above this is the accommodation for animals.

Connected with the autopsy room is a cold storage plant with accommodation for 12 cadavers, and by means of a brine circulation, refrigerators in the staff laboratories on the first, second, and third floors are kept cold. For many of the laboratories, too, there is a compressed air service.

The Anatomical Building consists of four storeys and a basement except at the north end, where there is a large lecture room, two storeys in height and capable of accommodating 250 students. Beneath the lecture room are several well-lighted and commodious rooms which are equipped as a laboratory for experimental surgery. The remainder of the basement gives ample space for the preservation and storage of material and for workshop. On the first floor are a chart room and a photographic room, and two study rooms. On the second floor is a commodious museum occupying the south end of the building, with a preparation room in connexion. Two laboratories planned to accommodate classes in histology, embryology, and neurology are also provided upon this floor, together with a second lecture room with seating accommodation for 100 students, and two demonstration rooms. On the third floor are a library, private rooms for the staff, a dissecting room, and a room for X ray demonstration. Another dissecting room is on the floor above.

FIG. 21.—TORONTO GENERAL HOSPITAL.



View of grounds—public wards.

clinical teaching suggested by these cases is provided by the staff each morning.

The Medical Building is three storeys in height in front, with an additional storey and sub-basement in the wings, which extend eastward. Two large lecture rooms are provided which flank the main edifice; the larger has accommodation for about 350 students; the smaller for about 200 students. The three main floors are arranged on the unit system, a unit room being 30 ft. long by 23 ft. deep, lighted on its long face by large windows. These rooms may be united so as to form large laboratories or may be cut in two where it is necessary. The Building is utilised for conducting the work in the departments of physiology, biochemistry, pharmacology, and zymology. In it are also the administrative offices of the Faculty of Medicine.

The Pathological Building is connected by a covered corridor with the out-patient department and so with the rest of the hospital. On the basement are the pathological museum, lecture room, and autopsy room; on the first floor rooms for the routine pathology, class-rooms for pathological histology and bacteriology, and the Department of Medical Research. On the second floor there are laboratories and rooms for the departmental library and special classes in pathology, in addition to laboratories for bacteriological and serological investigation. On the third floor are the class-rooms for systematic instruction in pathological chemistry and the laboratories for the

HOSPITAL TRAINING.

The greater part of the student's course is provided by the Toronto General Hospital, supplemented by attendance at the Hospital for Sick Children, St. Michael's Hospital, the Toronto Western Hospital, the Psychiatric Hospital, and the Riverdale Isolation Hospital.

Toronto General Hospital.—The hospital has 750 beds, and during the last year admitted to its wards 11,941 patients. The outdoor department, which has been elaborately equipped with especial attention to the requirements of teaching as well as treatment, is designed to receive and care for several hundred

patients each day, if necessity demands. Last year 67,358 out-patients were treated. The hospital is for the treatment of acute medical and surgical diseases, and the members of the staff are, in nearly every instance, drawn from the University medical faculty.

The hospital block contains ten acres, and the group of buildings includes almost everything necessary to enable a student to acquire a practical knowledge of the profession of medicine. On the south-west corner is situated the large pathological building, which is also an integral part of the hospital. In it are found the pathological, clinical, and chemico-pathological laboratories, as well as the autopsy room and the museums. The Pathological Building is regarded as one of the most complete in America. There were 304 autopsies during the year. North of the pathological unit is found the out-patients' department already referred to; then follows the emergency hospital, fully equipped with every modern device necessary for the immediate care and treatment of emergency patients. In this building arrangements have been made for the teaching and demonstration of practical methods in minor surgery.

The medical wing, the administrative building, and surgical wing embody every modern requirement in hospital equipment, and special facilities for the student are provided. Twelve operating rooms are to be found in the different surgical sections. South of the surgical wing is located the obstetrical hospital with 80 beds. The number of births in this department last year was 1332. To the X ray department more than 100 patients a day are sent in for examination, and complete courses are given to the students in X ray work. A well-equipped hydrotherapeutic department is connected.

Hospital for Sick Children.—This hospital, with 262 beds, has been remodelled and a large new wing has been built on the west side of the present building. These alterations and additions include new operating theatres, out-patient department, pathological laboratories, and wards for infectious cases.

St. Michael's Hospital.—This is a general hospital where medical, surgical, and obstetrical cases are admitted. The number of patients admitted last year was 4710, while 40,282 cases were treated in the out-patient department. There were 462 births in the obstetrical department. The accommodation has been enlarged by the addition of a new wing, so that there are now 383 beds.

Toronto Western Hospital affords excellent opportunities for clinical study. There is an outdoor service where dental, tubercular, surgical, medical, gynæcological, and special clinics are held. Two large operating theatres are provided and there are four public wards for clinical teaching.

The *Toronto Psychiatric Hospital* receives mental and nervous patients from the City of Toronto, especially milder types, for short periods of observation and treatment, and determines the best method of disposal of other cases which may not be suitable for admission to the hospital. Persons coming before the courts and suspected of having mental disability are remanded to the psychiatric hospital for observation, on the basis of which disposal is determined. The activities of the hospital are closely affiliated with those of other hospitals, with the psychiatric service in the public school system, with the juvenile court, and with the local and national committees in mental hygiene and the various social service organisations in the city, in linking together public health activities in the field of mental hygiene. There is accommodation for 30 male and 30 female in-patients, there being on each ward 20 beds in open wards and 10 single rooms.

Both in the out-patient department and in the wards opportunity is provided for instruction in psychiatry for students in the later years in medicine.

Riverdale Isolation Hospital has 375 beds where the study of the diagnosis and treatment of acute infectious diseases can be carried on. It is under the authority of the Local Board of Health, and the direct supervision of the medical officer of health of the city.

SOME REFLECTIONS.

As was indicated in the preliminary statement, the general pattern of medical education in the United States and Canada bears a strong resemblance to that prevailing in this country, where, however, closer homogeneity results from the existence of one body, the General Council of Medical Education and Registration, which has controlling powers. The details given in the sections dealing with the 14 medical centres which were visited show sufficiently that everywhere in the United States the attempt is made to provide for the medical student an education which should alike be scientific and of public utility, but variations of method, while preserving this common ideal, may be noted in this or that centre as they are reflected in the particular statements.

The Duration of Training.

Nowhere will the medical curriculum be found to be of less duration than that which is prescribed by our own General Medical Council, and for the most part the training is actually longer. In those cases where the medical course proper only lasts four years, as against the British term of five years, it will be seen that the pre-medical education, necessary to gain admission to any school, demands a knowledge of the fundamental sciences—that is, chemistry, physics, and biology—and that in only one case is the course, as far as these pre-medical subjects are concerned, of less than two years' duration. So far as this pre-medical course is concerned with scientific subjects it may be taken to represent the first year of the British medical curriculum, so that the addition of the four years' medical training in applied science and clinical work brings the whole professional curriculum to at least five years. No curriculum of less duration than this would be sanctioned at any of the medical centres which aspire to be considered of first-class standing, such as those that were inspected.

The Standardisation of Medical Schools.

And it may be pointed out that for many years a process of purging has gone on in the United States under which the inferior medical schools have been eliminated in a thorough way. As recently as 1906 there were 162 medical schools in the United States, and the training received by the students at some of these places was of a sort to bring all medical education into ridicule. The doctors in the United States suffered at home by having within their medical body members whose scientific and clinical attainments were very poor; and they suffered abroad by finding that claims to recognition by their own citizens in foreign countries were not admitted. This state of affairs, which in certain places had become a scandal, is now largely remedied, and to-day but 80 medical schools exist, and these have been submitted to a scheme of category under which only 72 are placed in the first class.

A system of education now prevails in the representative centres which is generally of a high standard and is carried on over a period which should certainly be long enough to enable the student, when graduation is reached, to serve his calling in accordance with public claims and assist in its scientific development. But it will be noted how great a stress is laid in the medical schools of the United States upon the amount of time that the student spends upon the various subjects of study, a stress that is entailed by the absence of a general system of examinations as we

understand examinations in this country. Where, as with us, the students of all the medical schools are assembled at regulated intervals to meet the common tests imposed by their universities or their corporations, the result of their training is all that they are asked to display, the question of how they were trained playing no part in the tests. The examinations have been standardised by a central authority, and periodical inspections by that authority are held in order to ensure that the standards are lived up to. Our Royal Colleges, whose diplomas, in one division of the country or another, are held by the great majority of our doctors, examine students coming from every medical school, ensuring that from the mass of the student material qualified men are drawn who can show a common and good level of accomplishment. This level, moreover, is not threatened by the multiplication of university medical Faculties which has been a recent feature in medical education, for, first, the university students receive their training at schools that are also training men and women who are not connected with a university, and, secondly, the university students in most cases acquire the College diplomas. To-day with us a doctor is a doctor and, save where the possession of an honours qualification is needed for the holding of an appointment, the particular affixes to a name in the Register have no significance.

The Rôle of External Examinations.

In the United States and Canada the rapid but unequal rises in culture, which are inevitable in the expansion of young countries, make any such centralisation impossible for the present, with the consequence that the medical students from one centre are not associated with those from another centre by meeting any common tests of knowledge, whereat they would display the results of the training received at their various centres to external examiners. Consequently the responsibility of deciding what man or woman is or is not fitted to become a member of the general body of practitioners, for the good alike of the public and of our calling, is placed upon the educational authorities of the individual school; and these authorities, in their character of internal examiners, bring to their assistance a close inspection of the conditions under which the work of the students is done, while regarding the examinational outcome of its doing. Hence the student is asked to occupy his time in certain ways, and this in such detail as to make it believed sometimes that the hours spent over a course can be correlated with the successful acquisition of knowledge. The authorities of the schools are well aware that such correlation can never be an accurate one; but insistence in the educational schedules upon proofs that a fixed time has been spent by the student in this or that direction helps to take the place of a system of external examiners, which cannot as yet be devised as a practical policy.

The Common Pattern Displayed.

At the 14 first-class centres visited the training proceeds in the usual three stages—i.e., it is concerned with: 1. Purely scientific subjects (in the United States and Canada taken in the act of matriculation). 2. Scientific subjects directly applicable to medicine—namely, anatomy, physiology, and biochemistry. 3. Pathology, or the variations from those normal standards with which work of the second period has familiarised the student, as they become related to clinical procedures at the close of the curriculum. The way in which these three stages are divided from one another at all the schools is that with which we are familiar in this country, but we find more attention is paid in the Western curriculum than in ours to the need for continuity. The order in which the subjects are presented to the American medical student varies from that at our schools mainly in the wish to preserve a sequence, the student being introduced to pathological and clinical work when he would not be considered with us sufficiently informed to benefit by such studies, or receiving lessons in psychology while learning histology. Every educational course has to consider numbers and not individuals, and it may be that precocious information fits the mind of one student while bewildering that of another. Hence criticism of any scheme, that at one place it is too fast or that at another place it is too slow, or too much planned in water-tight compartments, is not safe. We have here a real problem for the educationalist, but unluckily his opinions should be based upon evidence which he can seldom obtain, for he should be able to compare the success in after-life of large groups of students, starting their work at the same time, but pursuing it at different schools. In the United States such a big personnel appears to surround some of the principal teaching centres that an inquiry into the matter might well be started.

The Student Material.

The schedules set out in the preceding pages suggest on the face of them that the medical students of America and Canada form a more highly selected material than our medical schools obtain, for almost invariably it is remarked that the number of applications to enter any medical school exceeds by 5, 10, and even 12 times the number of those for whom admission can be found. The figures cannot be taken at their superficial value, if only because the rejected at one centre become the accepted at another. The reports that great numbers of students are being turned away from medical schools, while true in a sense, greatly exaggerate the situation, as can be seen from an investigation made two years ago by Dr. B. D. Myers,[1] whose figures showed that sifting processes resulted in the admission of the better element and the rejection only of a proportion of students less well qualified, so that the regulations for admission to the profession are not the deterrents that they have been thought to be.

The rejection of applicants for admission is carried out by strict scrutiny at all the 14 centres visited, and this procedure is entailed upon the authorities by the fact that the training of the accepted students will lie entirely with them; they will teach them, will promote them or suspend them, and will adjudicate upon their fitness for graduation without appeal to any but individual instructors. The sense of responsibility, thus implied, is displayed at the beginning by ascertaining all that is possible about the student. At the different schools different demands for information are made, but in addition to the production of credentials in proof of the quality of pre-medical education, all the schools expect some personal knowledge of the character and general make-up of the applicant, and at some a personal interview with the dean is required. The close relations thus opened up between the dean and the student are imitated in later phases of the curriculum by the association that occurs between the student and his teachers. Not only, considering the size of the institutions and the number of beds in the hospitals, is the total number of entrants to these schools each year light in proportion to the material opportunities for medical

[1] Myers, B. D.: Bulletin A.Am.M.Coll., April, 1927, ii., 97 July, 1928, iii., 193.

education, but this total comes soon to be split into groups so small that every man obtains what amounts to individual instruction, while the value of his work is watched and reported upon with a view to his place in some category of merit whereon his promotion will depend. It follows that in every stage of his career the way that the student does his work, as well as the outcome of that work, is being taken into account, a condition that cannot occur when the issues are being practically determined by external examinations.

The Examinational Test.

The most striking difference between the medical educational course in America and Canada and that in the United Kingdom is the method at which the teaching authorities arrive at their conclusions as to how far the students are benefited by their training, and how far they are fitted for the service of the public as qualified medical men. Absence of anything corresponding to formal examinations of students at regulated times is replaced by a sifting process that is always going on; and, save for the post-graduate procedures to obtain a State or Provincial licence, there are no external examiners.

Many in this country are found saying that the examination system with us is overdone, and the fact that the duration of a curriculum which is five years by statute is over six years in reality supports the largely held opinion, while this is strengthened whenever the results of some particular examination present a strikingly high average of failures among the competitors. The possible over-loading of our curriculum, accompanied by redundancy of examinations, has received the serious attention of the General Medical Council, but the difficulty for the Council of making the path of the student smoother is aggravated by the fact that there is at least as much pressure brought upon the Council to add to as to subtract from the compulsory schedules. As our art and science enlarge their boundaries many persons, in the spirit of true progress, desire that those developments should find representation among the questions of examiners—in the words of a popular sport, they desire to stiffen a course, which already appears too hard, by the lengthening of certain of the holes or by the provision of more obstacles. That difficulty is met both at home and abroad by the institution of post-graduate opportunities; but while post-graduate instruction is an extensive and well-organised affair in the United States, and while in Canada similar tendencies are manifest, in Great Britain the outcome of much talking has not been proportionate.

What things can safely be left to a post-graduate stage is to ask at the end of the educational curriculum the question which already exists at the beginning—namely, where the line should be drawn defining the medical course. Several of the American universities appear to provide an eight years' course, the total being arrived at by adding four years of pre-medical study to four years of medical study, and many of the schools insist also on a year's residential work before graduation. With our own pattern this course of eight or nine years becomes five years by deciding that of the four years of pre-medical work only the equivalent of one year is necessarily allocated to the study of chemistry, physics, and biology. But such simplification cannot be pursued all along the line, and at several of the American universities it would be impossible under their printed regulations; so that we see that the real place where the medical course proper may be said to start, taking all three countries into consideration, is not exactly certain. Turning to the other end of the curriculum we find that at some of the various centres noted there is much stress laid by teachers upon the knowledge displayed by the students along special lines; indeed, to many British teachers there must appear to be the risk here of a too early and easy detachment of the student's intelligence from the general in favour of the particular. Those who hold this view will also feel in respect of the British curriculum that attempts to add compulsory subjects, whose study must be covered theoretically in five years to the satisfaction of examiners, are on the wrong track, and that post-graduate training is required to meet the case.

In all cases in the United States the students are examined, as far as graduation is concerned, by their own teachers at their own centres, and the personal knowledge by the examiners of the kind of individual student they have before them influences the decisions. The sifting of the men in the pre-medical stage does not prevent a large proportion of the students from dropping out before graduation. The facts are recorded in a card-index of the Students' Register kept by the American Medical Association, from which it is learned that about 90 per cent. of all students who failed to graduate dropped out in the first two years of the medical course. "If, for scholarship or other reasons," says the *Journal of the American Medical Association*, "students are not qualified for the practice of medicine they should be notified in the earlier years so their time may not be wasted by vain attempts in the higher classes, only to be dropped after they have come so much closer to graduation. This not only adds extremely to their disappointment, but also prevents them from making a better use of their time in some other line of human activity."

These words form the most substantial argument against a completely external examinational system; such external tests cannot take note of much that counts, and time is wasted in vain effort. The fact that we possess here in the General Medical Council a single controlling authority functioning under the Privy Council to settle the standard and conduct of examinations makes possible our large and almost complete system of external examination, though there are signs that the internal examiner is gaining in influence with us. The institution of such a body in the United States is quite impossible along similar lines for the individual States could not be found surrendering so many privileges which now accrue to them, nor in Canada are the Provinces ready either to form a central body for themselves or to sacrifice their own initiative sufficiently to fall under the ægis of the General Medical Council.

Licences to Practise.

One consequence is that the various States and Provinces institute for themselves separate schemes of examination according to which separate licences are issued for legal practice in particular divisions of the countries, and here it may be said the principle of external examinations at last shows itself. The students will have graduated to the satisfaction of tests applied throughout their curricula by their own teachers, but to obtain the State or Provincial licence they have to satisfy boards of external examiners. These boards are of very different constitution and the form of examination instituted varies with each State or Province, although there is in America a central board of federal character whose examinational tests are accepted at certain of the larger or older States. It is outside the scope of these notes to comment further upon the licensing process in either

of the countries, but mention is made of its existence because examining boards instituted under it are sometimes alluded to as a proof that external examination is not so entirely unknown as one is usually led to believe, and that even a central body exists. In truth these examinations have almost nothing to do with the educational course of the student proper; the fact that they have to be passed has little or no influence upon the training which the student receives, though occasionally the statement is made, in connexion with the subject of hygiene, that in the tests for licences acquaintance with some of the topics which fall naturally under this heading will be expected.

FIG. 22.—UNIVERSITY OF CHICAGO: FIRST UNIT OF HOSPITAL GROUP.

The Hospitals and the Universities.

Next to the absence of a recognised system of external examinations at regular periods the most striking difference between the educational courses in America and Canada and the conduct of undergraduate training in the United Kingdom is produced by the fact that the schools where the students are trained are integral parts of some university system. Accordingly many of the hospitals at which the clinical work is done are not in their general constitution analogous to the great medical charities whereat our medical students are educated. In the excellent presentation of hospital data made by the Council on Medical Education and Hospitals of the American Medical Association the hospital service in the United States is divided in accordance with the standing of the institutions, or as the hospitals are centres for general education, or for the training of residents in connexion with a fifth year of the medical course, or according to whether the type of service rendered is general, special, and so on; further, the service is also classified according to "ownership or control." Under this heading hospitals may be subdivided as Government owned, as having certain educational functions, as publicly provided, as independently organised, or as belonging to religious denominations, fraternities, or industrial corporations. Certain States have built large hospitals, generally in connexion with a State University, to serve the double purpose of caring for the sick and injured throughout the State and to afford teaching material for the medical Faculty of the State University.

Examples will be found in the notes upon the different hospitals in the United States and Canada where the students receive their clinical training, of institutions which belong sometimes entirely to a university, sometimes entirely to a municipality, and occasionally entirely to a State. Now in so far as proprietorship brings with it privileges as well as responsibilities, it is clear that the appointment of the medical staffs of these institutions must be made on varying principles in accordance with the constitution of the institutions. This is a matter which has to be kept before our minds when the question arises as to the inter-connexion between a teaching hospital and

a university Faculty; it is a vital matter when we are considering medicine as a fit province for purely academic training in the manner that, for example, it is being considered at the University of Chicago (Fig. 22, and p. xxv). These large issues are not, of course, under discussion, but it is pertinent to point out that neither in the United States nor in Canada any longer can a first-class medical education be obtained save through a university school, even though that university may be incomplete in its number of Faculties.

A simple way of looking at this situation is to recall the historic connexion in our own country between the hospital and the medical school and then to look at the will of Johns Hopkins (see p. xxi). With us the medical school arose as a part of the hospital as far as the clinical departments of medical education are concerned; and when the schools arrived little but clinical facilities were contemplated. Thus, and quite literally, the hospital owned the school, and the authorities of the hospital made the appointments to the staff of the school as they did to the staff of the hospital. And these things remain so to-day in the main, though, as is well known, the introduction of the university element has now been effected. With us connexion with a university is no part of the original constitution of the hospital, while the students from universities who use the hospital medical schools do so upon terms—i.e., they pay for the training which they obtain at these large charities because the university, under whose provisions they intend to graduate, requires from its alumni knowledge in certain provinces where only a hospital can afford it. The principle laid down by Johns Hopkins envisages an entirely opposite position. The university enters as a senior partner, owns the hospital, and admits to the wards its own hospital students of its own school. A striking difference at once occurs in the staffing of the hospitals, for while with us the university teachers are not necessarily members of the staffs of the hospitals, in America and in Canada, speaking generally, the hospitals are staffed by the university professors. No difficulty whatever can arise about this when the university owns the hospital, while where the State owns the hospital the views of the State and the university are easily made to coincide as to the elections to the staffs. Where universities use the wards of great municipal institutions the situation is not always so simple, but at the huge hospitals visited at the 14 medical centres in the United States and Canada working arrangements had been made upon harmonious plans.

In Conclusion.

In conclusion, there is made no attempt to formulate conclusions, for a limited and quick survey of large things, involving estimates of academic ideals and of material plant alike, could result in nothing of the sort that would be useful. The wish has been to afford the information necessary to appraise how far the standards of medical education at a group of representative medical schools in the United States and Canada approximate to the standards in Great Britain, and to indicate the main differences so that measures of reform on both sides might be helped by making comparisons.

Many hold that in this country our examinational system is too rigid, while many thinkers in America and Canada regret the absence of some such machinery. With us to regard the hospital as an adjunct to university education is a view that has met with no general acceptance, though the advisability of establishing a close relation between the work of the ward and that of the laboratory is acknowledged; in America and Canada the medical school is an integral part of the university which controls the teaching given in the hospital. Here are two fundamental divergencies worth inquiry upon common grounds.

The story of money on the two sides of the Atlantic is not the same, but no one can say that the one or the other side is wholly at an advantage. The advance of medicine and medical education, in America particularly, is accompanied with a riot of expenditure; dollars seem to flow there as naturally for hospitals and laboratories as gold flowed in mediæval Europe for the great cathedrals; yet all this expenditure in a comparatively new civilisation may not be well directed, and, indeed, may have the danger that accompanies too rapid growth. We have, for our part, too little money but greater experience and greater right to rely upon precedent. Yet for these very reasons we may be too reluctant to adopt measures that would bring about progress.

Nothing but good can come from the endeavour of the great English-speaking peoples to understand each other on such matters On both sides of the Atlantic a simple chant may be heard to the effect that "the more we get together the happier we shall be." In reference to the calling of medicine the jingle is true, and *pourparlers* now taking place through the General Medical Council are concerned with practical measures of a coöperative sort.

VALENTINE'S MEAT-JUICE

In **Epidemic** and other **Diseases** of the **Tropics** in which there is great **Exhaustion,** excessive **Anaemia** and extreme **Irritability** of the **Digestive Organs, Valentine's Meat-Juice** demonstrates its **Ease of Assimilation** and **Power** in **Restoring** and **Strengthening.**

Albert Wilberforce Shepherd, *Glamorgan, Wales, Late District Medical Officer, Assam, India:* "I have used VALENTINE'S MEAT-JUICE in Assam, India, both in cases of Cholera and Dysentery and found it most efficacious; and in Wales, both during and after an attack of severe Influenza. I have found that in the former the stomach retained the preparation when all other things failed, and that in the latter, my patients had far less of the weakness usually complained of."

W. B. Scranton, M. D., *Medical Supt. Korean Mission Methodist Episcopal Church, Seoul, Korea:* "A most excellent use I frequently put VALENTINE'S MEAT-JUICE to, is tiding Babies through Cholera Morbus and Inanition. It acts at once and many a crisis has been passed safely, through the agency of VALENTINE'S MEAT-JUICE. It has also been of great value in my practice in the Far East in the treatment of that form of Summer Diarrhoea known as Sprue, where it tides the patients over until they can get to a better climate and the change of climate rectifies the rest."

For sale by all Chemists and Druggists.

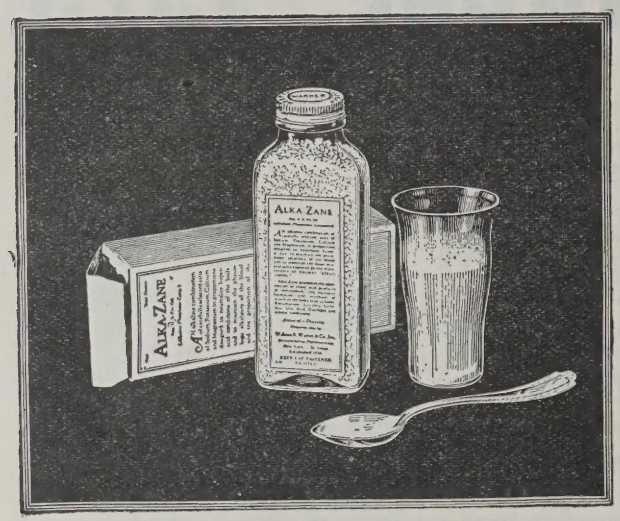
ALKA-ZANE



A pleasant, effervescent granular preparation composed of carefully selected salts of Sodium, Potassium, Calcium and Magnesium in physiologically correct proportions.

is a palatable and rational antacid, indicated in all conditions of relative hyperacidity, rheumatism, gout, intestinal, gastric, and certain cutaneous disorders.

Prompt in action, lasting in effect, it promotes diuresis, neutralizes excess acid production and helps to rebuild the alkaline bases.

The efficiency of Alka-Zane is demonstrable by the briefest of trials.

A supply for clinical use and literature sent gratis to physicians on request.

Manufacturing Pharmacists Since 1856.

PLASMONA

THE BLOOD & NERVE FOOD

is the **sovereign Restorative** and **Nerve Tonic** in convalescence, general debility and exhaustion, and during physical and mental overstrain.

PLASMONA

IS VERY SIMPLY PREPARED

by mixing one large heaped teaspoonful to a paste with a little **cold** water, then adding a quarter to half cupful of **cold** water or, preferably, milk.

HOT LIQUIDS MUST NOT BE ADDED

as the heat, besides affecting the flavour, would partially destroy the valuable vitamin content, so carefully preserved during manufacture by the use of the latest vacuum plant.

CLINICAL SAMPLES ON REQUEST.

Regesan

CREAM of MAGNESIA with LIQUID PARAFFIN

(Contains 30% of Liquid Paraffin)

An excellent combination of two proven remedies—exhibiting the advantages of both and minimising the tendency of Liquid Paraffin to leak. It is an emulsion, free from oily taste, in which the Liquid Paraffin is held in a very finely divided state, and as such is suitable for the treatment of Constipation with which digestive troubles are associated.

Regesan Cream of Magnesia with Liquid Paraffin forms a soft, easily evacuated fæcal mass and is particularly useful in the treatment of Hæmorrhoids.

Price 1/6 per bottle.

Full size trial sample free on application by postcard to Boots the Chemists, Station St., Nottingham.

TESTOGAN

FOR MEN

Formula by Dr. Iwan Bloch.

Special Indications for Testogan.

Sexual Infantilism and Eunuchoidism in the male. Impotence and sexual weakness. Climacterium virile. Neurasthenia, hypochondria.

THELYGAN

FOR WOMEN

Formula by Dr. Iwan Bloch.

Special Indications for Thelygan.

Infantile sterility. Underdeveloped mammæ, etc. Frigidity. Sexual disturbances in obesity and other metabolic disorders. Climacteric symptoms, amenorrhœa, neurasthenia, hypochondria, dysmenorrhœa.

In ampoules for intragluteal injection, also in tablets.

Atocin

In 7½ grain Tablets.
With Aspirin
5 grains Atocin,
2½ grains aspirin.

Rheumatism

Gout, Lumbago, Neuralgic and Sciatic Conditions respond favorably to the acidum phenylcinchoninicum product: Atocin. Unsurpassed for pain-relieving qualities and as a uric acid eliminant.

ELIXIR NEUROGENIC

(Cavendish)

In the Correction of Sexual Disabilities

particularly when associated with nervous phenomena, has proven of more than ordinary worth.

Under its use the appetite improves, sleep becomes more normal, the gastro-intestinal function more regular and depression lessened.

The sexual function takes on added vigour, and the patient by degrees finds himself more capable of discharging his usual duties.

ELIXIR NEUROGENIC (CAVENDISH) is a combination of the glycero-phosphates of calcium, sodium, etc., and of strychnine glycero-phosphates.

Extensive Literature and Case Reports on request.

CAVENDISH CHEMICAL CORP., 137, Regent St., London, W.1

or BUTLER & CRISPE, Clerkenwell Road, E.C. 1.

Corpora non agunt nisi Fluida.

Dr. Joseph James, D.D.S., F.R.C.S., D.Sc., M.S.A., once wrote of ODOL as follows:—

"I have studied the effects of ODOL Mouthwash outside the test tube under circumstances which at least approach those of the oral cavity. In testing a mouth-wash the attention should naturally be fixed exclusively upon the effect in the mouth itself. It is true that Miller has already laid down this rule as a guiding principle for testing the hygienic value of antiseptics intended for use in the mouth. Halliday very aptly remarked, 'It is quite evident that an antiseptic which might serve for the disinfection of refuse from slaughter houses, for infected cattle sheds, or for other similar purposes, must satisfy requirements entirely different from those of an antiseptic which is to serve as a cosmetic mouth-wash for daily use.' The ODOL antiseptic is evidently chemically related to the Salol of the Pharmacopœia, but it is essentially different from Salol as Parker of Bradford has demonstrated. ODOLISED SALIVA HAS A MINIMAL ALKALINE AND NO ACID REACTION. That ODOL in no way attacks the teeth is a fact admitted on all sides."

Mistol
FOR THE NOSE AND THROAT

MISTOL and the Mistol Dropper are a real advance in nose and throat therapy. Menthol, eucalyptol and camphor are combined in a specially prepared petroleum base which keeps these soothing and healing ingredients in direct contact with the mucous membrane for a considerable length of time. Unlike douches, Mistol avoids any possibility of sinus trouble. With head tilted back, the patient should let Mistol drop into each nostril until it is felt to be running into the back of the throat. It is manifestly superior to salves which do not reach all parts of the mucous membrane.

Especially efficacious in coughs and colds, simple, congestive and catarrhal rhinitis, hoarseness, bronchitis, and laryngitis.

Sold in original sealed cartons containing a—

'Panopepton'

THE FOOD FOR THE SICK.

Supplies directly available energising food; especially designed to make no draft upon the strength of the enfeebled organism.

'Panopepton' contains, in stable agreeable solution, 24% of solids, derived by physiological hydrolysis from prime lean beef and whole wheat, in a scientifically balanced ratio.

'Panopepton' presents the entire nutritive elements of these foods, the nitrogenous extractives, protein derivatives, carbohydrates, the complementary minute accessory factors, mineral and catalytic, thus meeting the most modern conception of a comprehensive food.

'Panopepton' requires no preparation—is instantly available in a crisis.

Supplied in 12-oz. bottles.

For Ill Conditions of the Gastric Tract

ALOCOL

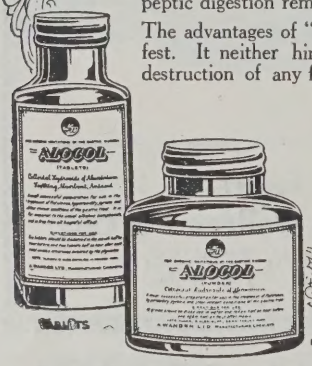
Colloidal Hydroxide of Aluminium

"Alocol" is the practitioner's safeguard when alkaline medication is indicated. Its clearly defined antacid properties exceed those of bicarbonate of soda, magnesia and subnitrate of bismuth; furthermore, "Alocol" eliminates all the unpleasant drawbacks which are particularly feared with the usual alkalis and oxides.

When "Alocol" reaches the stomach adsorption takes place; a colloidal jelly is formed, which, adhering to the walls of the stomach, diminishes their sensibility. The excess of hydrochloric acid is absorbed, but the acid reaction necessary for peptic digestion remains normal.

The advantages of "Alocol" are therefore manifest. It neither hinders proteolysis nor causes destruction of any food element or factor. Prolonged exhibition interferes in no way with the normal putrefactive function of the gastric juices or with the regular processes of nutrition.

"Alocol" is regarded as a specific in the treatment of hyperchlorhydria, whilst for all forms of fermentative dyspepsias with gastro-intestinal flatulence, acid eructations and other symptoms, common to gastric disease its influence is beneficial to the highest degree.



Complete chemical history of "Alocol" with convincing clinical reports, and supply for trial, sent free to physicians on request.

Oral Sepsis
and
INTESTINAL TOXAEMIA

The term Oral Sepsis was introduced by Dr. William Hunter in 1900 and sponsored by Sir Thomas Barlow in his recognition of it as the greatest septic infection in medicine. As the years passed a growing circle of believers joined in appreciation of Dr. Hunter's work and nomenclature, and in 1910 Dr. Mitchell Bruce in his presidential address said :

"Its effects are so widespread, so multiple, and frequently so grave as to make us ashamed of our previous blindness to a common source of blood infection staring us in the face all these years."

In view of the world-wide interest now taken in oral sepsis, the following extract from a letter, recently received by the proprietors of Dimol from a distinguished Fellow of The Royal College of Surgeons, should make a strong appeal to all Medical and Dental Practitioners.

" I have been using Dimol (tablets) and there is no doubt whatever that it is the very thing I have been trying many years to obtain, in order to settle a point which I have been considering for a long time.

" I believe it is generally assumed that the organisms which are responsible for Dental Caries and Pyorrhœa find their way to the intestine, and there set up putrefaction and fermentation, which cause the common symptoms of mal-digestion, and subsequent toxæmia (lassitude, headache, etc.). There seems to me another possible theory—viz., that Pyorrhœa is a *blood infection*, and that this infection may be directly attributable to a bacterial disturbance in the intestinal tract. I am inclined to this view because during a long career I have come across so many young people suffering from the intestinal symptoms first, and *then* getting Caries and Pyorrhœa.

" I am personally most grateful for Dimol." ————, F.R.C.S. (Eng.).

Dimol pulverettes are now supplied by the Admiralty for use in Royal Naval Hospitals and His Majesty's Ships.

VERONIGEN

A liquid preparation of the Hypnotic Barbitone or Diethyl-barbituric acid has long been desired as a useful means of procuring sleep. When given in reasonable doses it is claimed that it does not produce any toxic symptoms whatever, nor is cumulative in action, and in ordinary cases of insomnia one fluid drachm of VERONIGEN is sufficient dose for an adult. As a preventive of post-operative vomiting, one to two fluid drachms of VERONIGEN may be given one and a half to two hours before general anæsthesia is produced, and as a result much less of the anæsthetic is required. As BARBITONE has a slight diuretic action, the mixture can be used more safely than other hypnotics when the heart is weak. Where sleeplessness is a concomitant of pain, rest and relief can frequently be obtained by the administration of one drachm of VERONIGEN and two drachms of ELIXIR ACID. ACETO-SALICYLIC (Hewlett's).

DOSE FOR ADULTS.—One fluid drachm diluted, one hour before going to bed.
For Nervous Sleeplessness in Children.—10 to 20 minims diluted.
VERONIGEN. Price **10/6** per lb.

SHADOFORM

A preparation from which a liquid barium meal can be prepared at a moment's notice is of great value to the radiologist.

Shadoform is a soft powder with which a palatable meal of cream-like, non-gritty consistency is prepared merely by the addition of water; the meal is non-toxic, non-irritant, and retains its uniform opacity for a long period.

BARIUM SULPHATE B.D.H.

For the administration of a solid barium meal, efficacious yet free from toxic effects, Barium Sulphate B.D.H. is the ideal preparation.

T.I.P.

(tetra-iodo-phenolphthalein B.D.H.)

The sodium salt of T.I.P. is made specially for use in cholecystography. It is guaranteed non-toxic, every batch being tested in the B.D.H. physiological laboratories before issue.

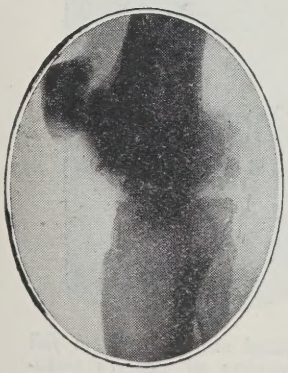
'IODOLYSIN'

Trade Mark

A Powerful Fibrolytic Agent

Strikingly Successful in Chronic Arthropathies



Radiograph of Knee-joint in Rheumatoid Arthritis

A fibrolytic agent which gives really satisfactory results in a large percentage of cases must appeal to the general practitioner who has constantly to deal with difficult and intractable cases of chronic rheumatism and allied conditions. This can be justly claimed for 'Iodolysin' which has a striking effect in Rheumatoid Arthritis; and it is also employed with advantage for the removal of all forms of pathological fibrous tissue.

'Iodolysin' is a chemical combination of Iodine and Thiosinamin with these special advantages:

Ready Solubility in water. Well tolerated. Absence of local reaction on injection

'Iodolysin' is supplied in ampoules for hypodermic injection; in capsules for oral administration, or as an ointment or paint for local application.

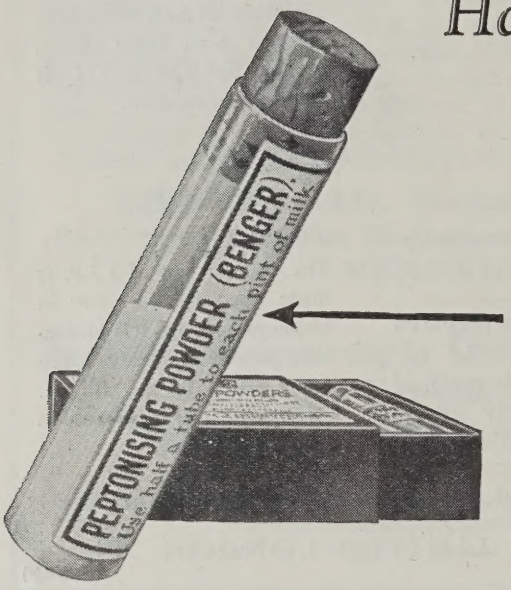
The most efficient Peptonising Powders!



Half a tube of Benger's is enough!

While half a tube of Benger's Peptonising Powders is enough to peptonise a pint of milk, gruel or soup, in most cases in 10 minutes, the extent of the peptonising action can be regulated by either increasing or diminishing the quantity of the powders, and by lengthening or shortening the time during which they are allowed to act on the milk, gruel, etc.

Generally speaking, Benger's Peptonising Powders produce the required result with half the quantity necessary of other preparations, whose initial cost also is higher.

Prices:
No. 1 — Box of 6, 1/-; No. 2 — Box of 12, 1/8

Benger's Liquor Pancreaticus.

An important aid in the preparation of Peptonised Milk, etc.

ANÆSTHETIC ETHER

—A NEW CHAPTER.

THE recent concession made by H.M. Commissioners of Customs & Excise permitting the use of *Duty-free* pure rectified spirit in the manufacture of ether, is a fitting climax to the strenuous efforts made by the late Mr. Thomas Tyrer twenty-five years ago to secure Duty-free Spirit for use in the British Chemical Industries. An interesting cartoon which originally appeared in 1904 was reproduced in last week's issue of the "Lancet," depicting Mr. Tyrer's work.

THERE has always been a certain prejudice against ether manufactured from methylated spirit being used for anæsthesia, owing to the possibility of traces of acetone, methyl compounds, pyridine and other injurious impurities being present. On the other hand, the high spirit duty rendered the use of ether made from rectified spirit impossible for general use, owing to its prohibitive price.

LONG experience as manufacturers of ether and elaborate methods of purification enabled Thomas Tyrer & Co., Ltd., to produce an anæsthetic ether which though prepared from methylated spirit was so highly purified that it was indistinguishable, both by chemical and physiological tests, from pure spirit ether.

ALL the same, the not unnatural suspicion remained in the minds of many anæsthetists that ether prepared from methylated spirit could not be so pure as that prepared from pure spirit. That lingering doubt can now be banished as Sterling Brand Ether for Anæsthesia is now made entirely from Pure Rectified Spirit and costs no more than the ether previously made from methylated spirit. Anæsthetists will use it with even greater confidence than before.

STERLING BRAND ETHER IS SAFE.

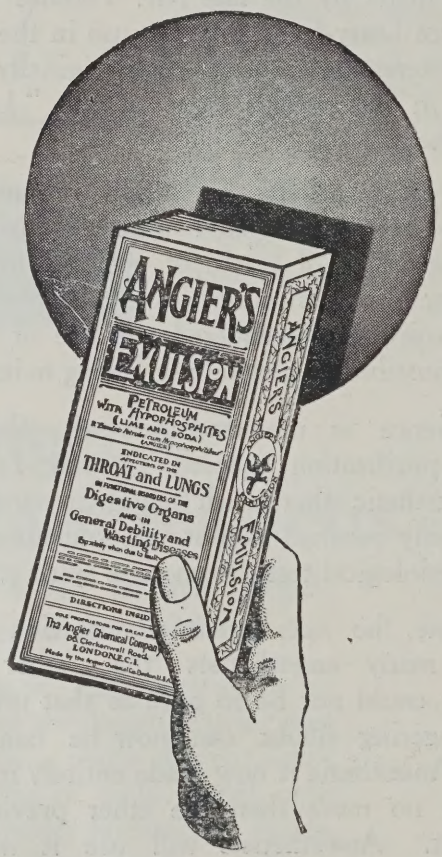
THOMAS TYRER & CO., LTD.

STRATFORD, LONDON, E. 15.

The most satisfactory form in which to administer Petroleum

Liquid Paraffin is repugnant to many fastidious patients because of its oily, greasy character. Occasionally it causes nausea and upsets the stomach. Frequently there is leakage which prohibits its continuous use. Even when taken readily and without these drawbacks, its failure to mingle with the food and with the fecal mass, lessens its full efficacy.

Angier's Emulsion is made with a specially purified petroleum of just the right degree of viscosity. It is palatable and freely taken by those who object to the plain oil; it does not nauseate or upset the stomach; it is readily miscible with water or milk; it mixes with the feces, keeping them soft and plastic and ensuring maximum lubrication; the characteristic action of petroleum is obtained with greater uniformity, Moreover *Angier's Emulsion aids Digestion and facilitates Assimilation.*



Thirty-seven years of clinical experience have demonstrated the foregoing so conclusively that countless physicians now look upon Angier's Emulsion as the most satisfactory and effective form in which to employ pure petroleum.

PLURIGLANDULAR DISPENSING

The choice of pluriglandular formulæ for the various conditions in which organo-therapy is indicated is often difficult. There may be a considerable difference of opinion as to dosage, and physicians may from their practical experience decide something quite definite but which is probably not in accordance with the usual formulæ.

The growing and varied needs of the profession in this respect are well catered for in our Organo-therapeutic Dispensary. A complete range of Gland substances is always in stock and prescriptions can be promptly and accurately dispensed.

THYMUS CO.

This is one of our recognised formulæ. It is put up in Tablets and in Elixir form, each dose representing Thymus sicc gr. 2, Thyroid sicc gr. $\frac{1}{8}$, Whole Pituitary sicc gr. $\frac{1}{10}$. It is suggested for the treatment of marasmic conditions and atrophy. In addition it may be employed in dealing with nutritional disorders, and defective development of bony or other tissues. Full particulars of this and other formulæ will be found in our brochure "PLURIGLANDULAR FUNCTION" which may be had on application to

Evans' Biological Institute, Runcorn.

OVALTINE

and the Milk Diet

"Ovaltine" relieves the monotony of the milk diet.

It increases the food value by fifty per cent.

It is an effective agent for adjusting the carbohydrate deficiency of milk.

The accessory food factors are present in "Ovaltine" in correct nutritive ratio and greatly enhance the nutritional value of milk.

"Ovaltine" renders possible food concentration in small volume, a valuable feature in conditions of difficult alimentation.

By the action of its malt constituent the dense heavy curd of cow's milk is converted into light, flaky, easily digested coagulum, and it has been conclusively shown by laboratory experiment that "Ovaltine" increases the digestibility of milk two fold.

"Ovaltine" is a highly concentrated extraction of malt, milk and eggs. One cupful when made as directed has a greater food value than 3 eggs or 12 cupfuls of beef extract.

A liberal supply sent free for clinical trial on request.

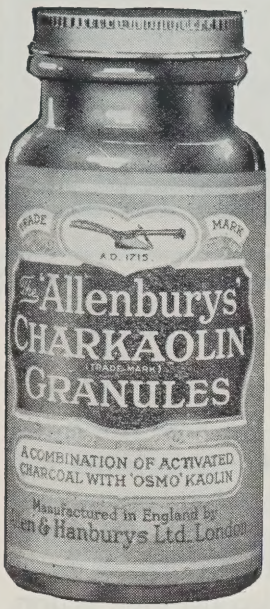
The 'Allenburys'



'CHARKAOLIN' GRANULES

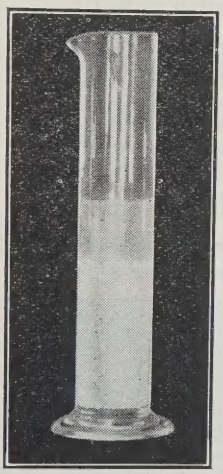
A Combination of Highly Activated Charcoal with 'Osmo' Kaolin

'Charkaolin' is a new and highly efficient agent for the treatment of intestinal infections characterized by abnormal fermentation and the formation of toxins. It combines the absorbent properties of highly activated vegetable charcoal with the well-known toxin adsorbing qualities of 'Osmo' Kaolin. It is in the form of fine, clean granules which disintegrate rapidly in water and diffuse their ingredients evenly throughout the liquid. 'Charkaolin' is tasteless, forms a fine suspension in water and is, therefore, quite easy to take.

Descriptive literature and a clinical trial sample will be sent on application.

ALLEN & HANBURYS Ltd., Bethnal Green, E.2

The 'Allenburys' DIET

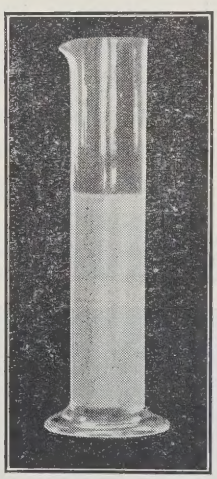


A Showing the heavy curd formed by the action of gastric juice on ordinary cow's milk.

A Stimulating and Sustaining Food Beverage

A solution to the problem of feeding in many acute and chronic affections is found in the use of the 'Allenburys' Diet, which presents distinct advantages over cow's milk both with regard to food value and digestibility. The 'Allenburys' Diet is a palatable and highly nutritive food beverage prepared from pure fresh full-cream milk and whole wheat, and is particularly easy of assimilation. It replaces with advantage milk and the milk dishes commonly employed in sickness and convalescence and can often be taken and retained where other foods are rejected. As a stimulating and sustaining beverage for people of all ages, it is infinitely superior to tea, coffee, etc. It can be made in a minute simply by adding either boiling water or milk.

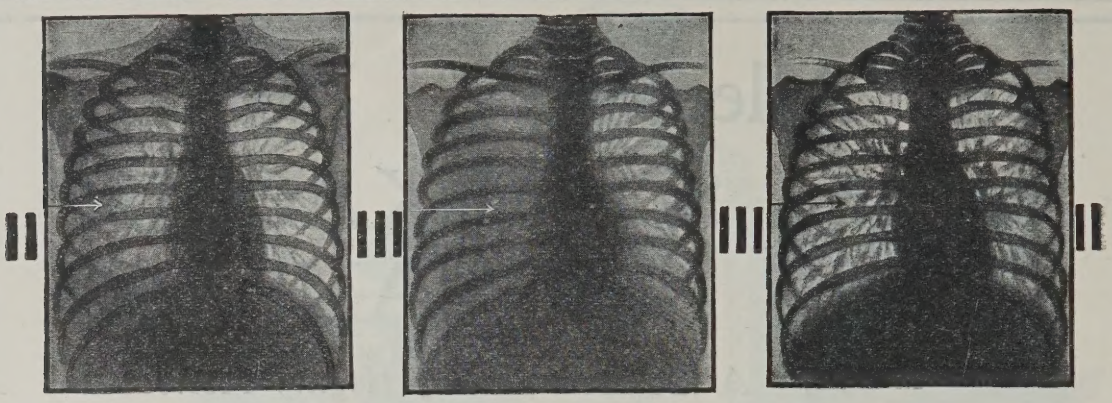
In tins at 2/1, 4/- and 7/6.



B Showing the finely flocculent curd formed by the action of gastric juice on the 'Allenburys' Diet.

Descriptive Literature and free clinical sample will be gladly sent on request.

ALLEN & HANBURYS LTD., Bethnal Green, London, E.2.



Which Type?

PREBLE points out that "of all the diseases which may be classified as typical, none is truer to its type than the pneumococcus pneumonia". The treatment of pneumonia, *whatever the type*, is essentially symptomatic. And symptomatic therapy is *necessary* in pneumonia, first, because it is not always possible to combat the *cause* of the disease effectively, and, second, because it is necessary to correct functional faults and to stimulate functional deficiency, both of which determine the course of the infectious process to a large extent.

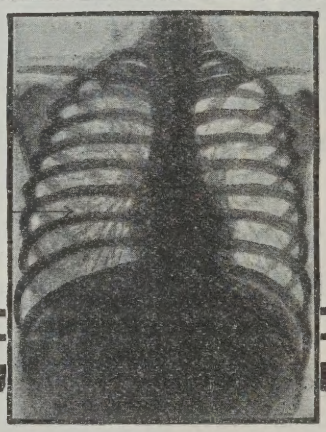
Whatever the type—

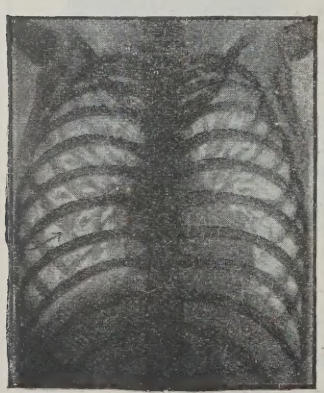
Antiphlogistine

is indicated.

Applied as a jacket over the entire thoracic wall, Antiphlogistine will serve to allay the painful pneumonic process, facilitate expectoration and ease the efforts of coughing. By virtue of its marked decongesting action, it sustains the vasomotors and the circulation, decreases toxemia and, being thermogenetic, assures a maximum of comfort with a minimum of disturbance to the suffering patient.

Every physician should have a copy of our brochure "The Pneumonic Lung" (illustrated in color), epitomizing the etiology, pathology and symptomatology (including roentgenographic chest plates) of the various types of pneumonia. Please use the form below for your free copy.





THE DENVER CHEMICAL MFG. CO., LONDON, E.3.

You may send me, free of all charges, your illustrated brochure, "The Pneumonic Lung", together with sample of Antiphlogistine for clinical trial.

A Notable Achievement in Anaesthetics

For many years Anaesthetists have demanded a pure Ether made from pure Rectified Spirit, but have not felt justified in paying the exorbitant duty which had to be included in the price. From this derived the constant fear that the impurities such as Wood Spirit, Pyridine, etc., authorised by the Customs as necessary denaturants in the preparation of Ether at an economic price, had not been completely eliminated in the final product, and the feeling that in troublesome cases the Ether used might be suspected.

Howards of Ilford have now made special arrangements with the Customs which enable them to supply their Standard Ether, ***manufactured entirely from Duty-Free Rectifed Spirit,*** which has never been in contact with ***any*** deleterious or objectionable denaturant at ***any*** stage, ***without extra charge.***

This is one of the greatest advances in the economic production of absolutely pure Anaesthetic Ether for many years.

When ordering Anaesthetic Ether please specify

HOWARDS' STANDARD ETHER

In $^1/_4$lb., $^1/_2$lb., and 1-lb. Amber bottles, and obtainable through any reputable Wholesale House.

SULFARSENOL

IN THE TREATMENT OF PUERPERAL FEVER

Since January, 1924, M. Riviere (Gaz. Hebd. Sci. Med., January 6th, 1929, p. 2) recommends the use of arsenic salts in the treatment of puerperal fever. Encouraged by good results he has, since 1925, aimed at the prevention of puerperal fever by the same means. Arsenic has been given in all cases in which fever might be expected. Riviere's figures for four years are 3,667 accouchements with only three deaths, giving a mortality of 0.08 per cent. ; of this number, 169 were definitely septic, though in varying degree. Among them were women who had had multiple interventions before admission to hospital, frequently without aseptic or even antiseptic precautions. The author has now arrived at a systematic method of treatment : at the first rise of temperature of genital origin, without waiting for absolute clinical confirmation, arsenic is administered ; subcutaneous injections of Sulfarsenol proved most satisfactory. For treatment 0.12 to 0.18 cg. in severe cases was given ; this dose was repeated from one to nine times according to the resistance and the gravity of the infection. For prevention 0.06 to 0.12 cg. was found to be adequate. Out of 53 important operations, treated on such preventive lines, in 7 cases there had been infection, and there had been only one death.

EPITOME OF CURRENT MEDICAL LITERATURE.—*British Medical Journal*, Feb. 23rd, 1929.

Literature on Sulfarsenol and a copy of " The Treatment of Puerperal Infection with the Salts of Arsenic," by Prof. Maurice Riviere, gladly sent on request.

BELLED MIRROR OF ANCIENT JAPANESE MANUFACTURE. THE MIRROR, STILL AN OBJECT OF RELIGIOUS HONOURS, WAS A VERY SACRED EMBLEM TO THE ANCIENT JAPANESE.—The mirror, symbol of the sun and concrete token of the presence of the sun-goddess, figures largely in Japanese myths. In one of these the sun-goddess gives the mirror to her grandchild, Ninigi, in sending him down to be the ruler of the world; she tells him to look upon it as her emblem or even as her actual self. The mirror was considered, also, to be the symbol of virtue and was buried with the dead as an amulet against decay. An especially sacred mirror mentioned in the Chronicles of Japan under the date 92 B.C. was an object of worship at that time; it was, later, enshrined at Ise, where it is still preserved with the greatest veneration. Sun-worship was the central feature of the early religion of Japan. Shinto, "the way of the gods" is, however, now almost extinct. Nevertheless, it served to give a religious quality to some of the principles which have led to stability in the state, *e.g.*, to the idea of reverence for the Mikado.

ULTRA-VIOLET IRRADIATION

THE value of irradiated milk for rachitic children and in cases of tuberculosis of the bones has been shown many times. (See B.M.J., March 28th, 1925; The Lancet, Jan. 2nd and Dec. 25th, 1926; The British Journal of Radiology, Feb., 1926; and the Journal of Actinotherapy, June, 1928.) But hitherto the process of irradiation has always tainted the final product.

This difficulty has now been definitely overcome!

by

The 'SCHEIDT' PROCESS

in which COLD QUARTZ TUBES

with remarkable U.V. spectra give an easily controlled and positive activation, and leave the products

UNCHANGED IN TASTE OR ODOUR

The only process of effectively Irradiating Milk without taint of Ozone and Carbon Dioxide.

The "Scheidt" Apparatus for cold tube activation is now installed, and in process of installation, at many of England's leading Clean Milk Farms & Dairies. These Farmers understand Milk and how it should taste where Infant Nurture is in question

They have adopted the "SCHEIDT" PROCESS!

Clinical, X-ray and Blood Tests, carried out by eminent medical men using only the "Scheidt" Cold Tube apparatus (as against Quartz Lamp), are available, and have been quoted in the literature of Foreign Competitors who appear to have thus paid an unconscious tribute to the value of the "Scheidt" Process.

Members of the Medical Profession are invited to a demonstration at

SOLVING A FOOD PROBLEM

HOVIS

the most nourishing Bread

After all the discussions as to the relative values of white, wholemeal and various brown breads it is satisfactory to have conclusive evidence at last.

Following many experiments by various research workers it is shown that no bread contains so large a percentage of Vitamin B as Hovis, or is such an active agent for healthy growth when forming the basis of the diet.

As is now well known, even a partial deficiency in Vitamin B in the diet, if lasting for any length of time impairs health and with children prevents perfect development.

Hovis even in small quantities provides sufficient vitamin in a digestive form as no other bread does, and it is liked by all.

Richest in Vitamin B

Hovis Bread consists of White Flour with the wheat germ incorporated. It is this which gives it its special value, since the germ is the part richest in the Vitamin.

The "Brownness" of bread is not a measure of its vitamin content. Further, the goodness of Hovis is fully absorbed into the system because, unlike wholemeal bread which has a tendency to pass through the body without the nourishment being properly extracted, Hovis contains no bran and is digested naturally and easily, retaining all its richness.

The evidence is conclusive. For providing the maximum of nourishment economically no bread equals Hovis.

HOVIS

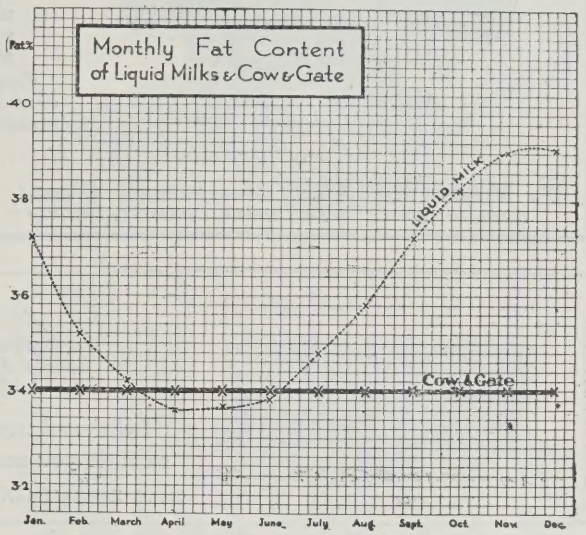
Best Bakers Bake it

HOVIS LTD LONDON & MACCLESFIELD

A RELIABLE BASIS



The above chart shows the large fluctuations in the fat content of liquid milks throughout the year, as compared with the unvarying content of COW & GATE which is based on the fat content of average healthy Breast Milk.

Fat Content in Cow & Gate reconstituted (1 in 8) 3·4%

Fat Content in Average Breast Milk 3·3%—3·5%

This is ONE of the many reasons why COW & GATE is the safest and most reliable alternative when breast feeding fails, and why it affords the most definite basis for Infant Feeding Modifications.

WHY FAIL at the F.R.C.S. England (Primary or Final)?

Enrol now for the Oral and Postal Revision Classes and make sure of success.

¶ The remarkable success of Students of the Medical Correspondence College at the higher Surgical Examinations is specially noteworthy.

¶ Both at the Primary and Final F.R.C.S. England the majority of our Students are successful at the first attempt, and Candidates who have failed at these Exams. on several previous occasions get through without difficulty after going through our courses.

¶ The Surgical Tutors of the College all hold either the M.S.Lond. or F.R.C.S. England, or both, and are highly experienced teachers.

¶ The Postal Courses are thoroughly clear, concise and up to date, and the test questions are carefully selected from those set at previous Examinations so as to embrace all parts of the subject. By working systematically through the Course the Student is brought up to the examination standard in the minimum time and much unnecessary reading is saved

ST. ANDREW'S HOSPITAL

FOR MENTAL DISORDERS,

NORTHAMPTON

FOR THE UPPER AND MIDDLE CLASSES ONLY.

PRESIDENT: THE MOST HON. THE MARQUESS OF EXETER, C.M.G., A.D.C.
MEDICAL SUPERINTENDENT: DANIEL F. RAMBAUT, M.A., M.D.

This Registered Hospital is situated in 120 acres of park and pleasure grounds. Voluntary Boarders, persons suffering from incipient nervous and mental disorders, as well as certified patients of both sexes, are received for treatment. Careful clinical, bio-chemical, bacteriological and pathological examinations. Private rooms with special nurses, male or female, in the Hospital or in one of the numerous villas in the grounds of the various branches can be provided.

WANTAGE HOUSE

This is a Reception Hospital, in detached grounds with a separate entrance, to which patients and voluntary boarders can be admitted. It is equipped with all the apparatus for the most modern treatment of Mental and Nervous Disorders. It contains special departments for hydrotherapy by various methods, including Turkish and Russian baths, the prolonged immersion bath, Vichy Douche, Scotch Douche, Electrical baths, Plombières treatment, &c. There is an Operating Theatre, a Dental Surgery, an X-ray Room, an Ultra-violet Apparatus, and a Department for Diathermy and High Frequency treatment. It also contains Laboratories for bio-chemical, bacteriological, and pathological research.

MOULTON PARK

Two miles from the Main Hospital there are several branch establishments and villas situated in a park and farm of 650 acres. Milk, meat, fruit and vegetables are supplied to the Hospital from the farm, gardens and orchards of Moulton Park. Occupation therapy is a feature of this branch, and patients are given every facility for occupying themselves in farming, gardening, and fruit growing.

BRYN-Y-NEUADD HALL

The Seaside house of St. Andrew's Hospital is beautifully situated in a Park of 330 acres, at Llanfairfechan, amidst the finest scenery in North Wales. On the North West side of the Estate a mile of sea coast forms the boundary. Voluntary Boarders or Patients may visit this branch for a short seaside change or for longer periods. The Hospital has its own private bathing house on the seashore. There is trout fishing in the park.

At all the branches of the Hospital there are cricket grounds, football and hockey grounds, lawn tennis courts (grass and hard court), croquet grounds, golf courses and bowling greens. Ladies and gentlemen have their own gardens, and facilities are provided for handicrafts such as carpentry, &c.

For terms and further particulars apply to the Medical Superintendent (TELEPHONE: No. 56 Northampton), who can be seen in London by appointment.

NEW SAUGHTON HALL

THE ONLY PRIVATE HOSPITAL for the TREATMENT of MENTAL CASES in SCOTLAND

POLTON, MIDLOTHIAN.

NEW SAUGHTON HALL, which takes the place of Saughton Hall, established in 1798, is situated seven miles south of Edinburgh, in the beautiful neighbourhood of Hawthornden and Rosslyn, and is surrounded by picturesque and well-timbered pleasure grounds extending to 125 acres.

Railway Stations—Polton, five minutes; and Loanhead, ten minutes' walk from the Institution—reached in half an hour from the Waverley Station, Edinburgh. Telephone—4 Loanhead.

Forms of admission for voluntary or certified cases, full instructions, &c., can be obtained on application to the Resident Medical Superintendent, JAS. H. SKEEN, M.B., C.M. Aberd. Inclusive terms from £165 to £500 per annum, according to requirements.

W. H. HEAD, Secretary-Superintendent.

Administrative County of Southampton

COUNTY MEDICAL OFFICER OF HEALTH.

The Hampshire County Council invite applications for appointment of County Medical Officer of Health from persons legally qualified for the practice of medicine, surgery, and midwifery and registered in the Medical Registrar as holders of a Diploma in Sanitary Science, Public Health, or State Medicine, under Section 22 of the Medical Act, 1886, and of an age not exceeding forty-five years at the date of application. The post is established for the purposes of Superannuation.

The person appointed will be required to devote the whole of his time to the duties of his office and not to hold any other appointment or engage in private practice.

He will receive a salary of £1250, payable monthly and all sums by way of fees or otherwise received by him will be paid over to the County Fund.

He will be provided with the necessary offices and clerical staff.

Applications on a prescribed form (which with further particulars of duties and conditions of appointment may be obtained from me) addressed to me and endorsed "County Medical Officer" must be delivered at the Castle of Winchester on or before the 20th April, 1929.

Canvassing, either directly or indirectly, is prohibited and will disqualify. F. V. BARBER, Clerk of the County Council.

The Castle, Winchester, March, 1929.

County Council of Durham.

DISTRICT TUBERCULOSIS MEDICAL OFFICER.

The County Health Committee invite applications for a District Tuberculosis Medical Officer, at a commencing salary of £600 per annum, rising by annual increments of £25 to £650 per annum. Travelling expenses will be paid by the County Council.

The appointment will be held subject to three months' notice on either side, and to the following conditions:—

(1) The officer appointed must be a registered Medical Practitioner between the ages of twenty-five and forty-five years, must devote the whole of his time to the duties of the office, and must not engage in private practice.

(2) He should have held a house appointment for at least six months in a general hospital and have had practical experience in the treatment of tuberculosis in sanatoria and otherwise.

(3) He will be attached to the County Health Department, and will, subject to the directions of the County Medical Officer, be under the control of the Central Tuberculosis Medical Officer

(4) He will be required to reside in his Dispensary area, or such other centre as required by the Council.

(5) He will be required to carry out the duties of a District Tuberculosis Medical Officer.

(6) He must be prepared, if called upon, to act as locum tenens to other members of the Medical Staff of the County Medical Officer.

(7) The holding of a Diploma in Public Health, and practical experience in bacteriological laboratory work, will be deemed additional qualifications for the post.

The candidate appointed will be required to pass the County Council's medical examination, and will be subject to the provisions of the Local Government and Other Officers' Superannuation Act, 1922.

Applications endorsed "District Tuberculosis Medical Officer," with copies of not more than three recent testimonials, must be forwarded on or before 5th April next to the County Medical Officer, Shire Hall, Durham, from whom forms of application can be obtained.

HAROLD JEVONS, Clerk of the County Council.

Shire Hall, Durham, 18th March, 1929.

Norfolk & Norwich Hospital, Norwich.

Applications are invited for the posts of:—

HOUSE SURGEON. Salary £120 per annum, with board, residence, and laundry. Preference will be given to a candidate who has held a previous Hospital appointment.

HOUSE SURGEON TO THE SPECIAL DEPARTMENTS (Ear, Nose and Throat and Ophthalmic). Salary £120 per annum, with board, residence, and laundry. Candidates (Male) who must possess registered qualifications, should forward applications, stating age, nationality, &c., together with copies of testimonials, to the undersigned, not later than Tuesday, 8th April, 1929. FRANK INCH,

22nd March, 1929 House Governor and Secretary.

City and County of Newcastle-upon-Tyne.

CITY HOSPITAL FOR INFECTIOUS DISEASES.
RESIDENT MEDICAL ASSISTANT (MALE).

Wanted immediately, a Resident Medical Assistant (Male) who holds a registrable qualification in Medicine and Surgery (and preferably also in Public Health), and possesses a practical knowledge of Bacteriology.

Salary £350 per annum, with board, lodgings, &c.

Applications, stating age, qualifications, and previous experience, to be forwarded with copies of not more than three recent testimonials to the Medical Officer of Health, Town Hall, Newcastle-upon-Tyne.

19th March, 1929.

Borough of Bexhill.

MEDICAL OFFICER OF HEALTH.

Applications are invited from duly qualified gentlemen for the appointment of Medical Officer of Health of the Borough, subject to the provisions of the Public Health Officers' Act, 1921, and the Sanitary Officers' Order, 1926.

The gentleman appointed will be required to perform all the duties imposed on a Medical Officer of Health, to act as School Medical Officer, and to carry out all such duties as the Council with the consent (if necessary) of the Minister of Health, may from time to time direct. He must reside in the Borough and devote his time to the duties of the office and must not engage in private practice.

The salary to cover all the duties specified above will be £800 per annum inclusive.

Applications stating age, experience, &c., accompanied by copies of not more than three recent testimonials, should reach the undersigned not later than the 6th April, 1929, endorsed "Medical Officer." S. J. TAYLOR, Town Clerk.

Town Clerk's Office, Bexhill, 19th March, 1929.

Carnarvonshire and Anglesey Infir-

MARY, Bangor (a General Hospital).—HOUSE SURGEON (Male) wanted. Must be fully qualified. Salary £200 per annum with residence, board, and laundry.

Special consideration given to candidates experienced in X ray work and administering anæsthetics. Duties to commence 1st May. Applications with two recent testimonials to reach the Secretary not later than April 4th.

Wanted for the Lady Hardinge

MEDICAL COLLEGE, New Delhi, India, from mid-September, 1929, a Medical Woman with experience in teaching Anatomy, to act for the Professor of that subject during her year's leave. Salary Rs. 750 a month with free furnished house, and free passage to and from India (the rupee is standardised at 1s. 6d.).—Apply, with testimonials, to the College Principal.

The Secretary of State for India

proposes shortly to make a certain number of APPOINTMENTS to Permanent Commissions in His Majesty's INDIAN MEDICAL SERVICE. A Selection Committee will meet at the India Office on 15th April to consider applications. Well-qualified Medical Men of European descent (British subjects), who desire to be considered, should apply to the Under Secretary of State for India, Military Department, India Office, London, S.W.1, for forms of application, regulations, and other particulars. Envelopes should be marked on top left corner "Medical Recruitment." The selected candidates will be required to undergo a course of instruction in this country, commencing on 29th April next, prior to embarking for India towards the end of the year.

Goculdas Tejpal Hospital, Bombay.

APPOINTMENT OF HONORARY SURGEON.

Applications are invited for the above appointment. Goculdas Tejpal Hospital (266 beds) is associated with the Grant Medical College, Bombay, for clinical teaching of undergraduates. The appointment carries an honorarium of R150 per mensem and will be for a period of five years, subject to termination by three months' notice on either side.

Applications, in duplicate, marked "Honorary Surgeon," stating age, qualifications, and experience, together with copies of three recent testimonials, must be sent so as to reach the undersigned not later than the 15th of May, 1929.

F. N. MOOS, M.D. (Lond.),
Superintendent, G. T. Hospital, Bombay.

Hong Kong.

A vacancy at present exists for an ASSISTANT MEDICAL OFFICER OF HEALTH, Hong Kong.

Salary £740 per anum, rising by annual increments of £30 to £1040 per annum, subject to deduction of 4 per cent. of salary towards the pensions of widows and orphans of Government servants.

The engagement is for three years in first instance. Free passages are provided. Furnished quarters, if available, are provided at a rental of 7 per cent. of the salary, or an allowance is given in lieu.

Private practice is not allowed.

Candidates, who must be British subjects of European parentage and not over thirty-five years of age, must hold a Diploma in Public Health. Forms of application may be obtained on application, in writing, to the Private Secretary (Appointments), Colonial Office, 2, Richmond-terrace, Whitehall, London, S.W.1.

Wanted.—Medical Officer for group

of Tea Estates in Assam. Candidates preferably about 30 or upwards, whose experience and qualifications must bear strictest expert investigation. Four years' agreement. Commencing salary Rs.1500 a month, rising Rs.50 a month each year, plus Rs.150 a month Car Allowance throughout (Rupee equivalent 1s. 6d.). Free furnished Bungalow, use of certain servants, first class passage. Write with fullest particulars to Z.M. 751, c/o Deacon's Advertising Agency, Fenchurch-avenue, E.C. 3.

Royal Isle of Wight County Hospital, Ryde.

A vacancy having occurred in the office of HONORARY SURGEON to the Ear, Nose, and Throat Department, the Election Committee of the Governors will proceed to fill the appointment. Candidates must not be engaged in general practice. Further details may be obtained from the Secretary, to whom applications must be addressed, and should be received not later than Wednesday, April 10th. Canvassing members of the Election Committee will be a disqualification.

A. S. GORDON, Secretary.

East Riding County Council.

ASSISTANT TUBERCULOSIS OFFICER.

Applications are invited for the post of Assistant Tuberculosis Officer under the East Riding County Council.

The gentleman appointed will be required to live at the Raywell Sanatorium (64 beds), where he will be Medical Superintendent. He will also be expected to carry out the duties of Clinical Tuberculosis Officer within the County.

The salary is at the rate of £650 per annum with emoluments valued for superannuation purposes at £100 per annum, subject to the statutory deductions under the Local Government and Other Officers' Superannuation Act, 1922. The emoluments are a bungalow, rent and rates free, also fuel, light, laundry, and garden produce.

Applications, accompanied by not more than three recent testimonials, must be made on prescribed forms, which can be obtained on application and must reach the undersigned not later than Saturday, the 13th April, 1929.

(Signed) J. R. PROCTER, Clerk of the Council.

County Hall, Beverley. March, 1929.

Tynemouth Union.

ASSISTANT MEDICAL OFFICER (Non-Resident).

The Guardians of the Tynemouth Union invite applications for the appointment, for a period of six months, of an Assistant Medical Officer for their Poor-law Institution, Preston-road, North Shields, and for the Children's Homes of the Union.

Salary £300 per annum, inclusive of vaccination and all other fees. The officer appointed will be required to pay to the Common Fund of the Union all fees received by him for inquests, certifying lunatics &c., to devote the whole of his time to the duties of the office (which includes the training of Probationer Nurses), to reside in close proximity to the institution and to act under the direction of the Medical Officer.

Applicants must be duly registered under the Medical Acts, and be qualified by law to practise in Medicine and Surgery in England and Wales, and the candidate appointed will be required to produce his licenses, diplomas, or certificates to the Guardians.

The appointment is subject to the provision of the Poor-law Officers' Superannuation Act, 1896.

Applications must be made on a printed form which will be sent on receipt of a stamped, addressed foolscap envelope, and must be returned to me, accompanied by copies of testimonials as to professional ability and personal character, by the first post on Saturday, the 6th proximo. By order.

TOM PERCIVAL, Clerk to the Guardians.

PRACTICES AND PARTNERSHIPS FOR SALE.

1. DEATH VACANCY.—NORTHANTS.—Country district, near large town. Mixed-class PRACTICE, producing about £1200 p.a., including panel of 800. Fees 3s. 6d. to 10s. 6d., with medicine extra. Midwifery 2 to 5 gns., about 20 cases yearly. Excellent well-built house, with 3 reception, 10 bedrooms, &c. Garden. Garage. Price for freehold £2500, £1500 of which on mortgage. Hunting, shooting, fishing, &c. Schools within reach. Premium one year's purchase, or near offer.
2. KENT.—Coast TOWN.—Small, but increasing middle- and working-class PRACTICE, producing for last 12 months nearly £600. Panel of 560. Visits 3s. 6d. upwards. Not much Midwifery at from £3 3s. Double-fronted eight-roomed house, with three-quarters of an acre of garden. Price for freehold £1400. Premium £900.
3. DEATH VACANCY.—WEST MIDLANDS, CATHEDRAL CITY.—Old-estab. good mixed PRACTICE, producing for last 12 months about £900, including panel of over 1000. Fees 3s. 6d. to 10s. 6d. Midwifery from 3 gns. Good house situated in best part of town, with 2 reception, 4 bedrooms, &c. Garden. Available on rent or by purchase; or if single, purchaser could board with widow. Sport of all kinds, and good schools. Offers invited.
4. LONDON, WEST-END. — PARTNERSHIP. — A One-fourth or One-third Share is for disposal in an old-estab. good-class, non-panel, non-dispensing Practice. Net income of share £1120. Fees 1 guinea upwards. Very little Midwifery from 31 gns. Suitable flat available for bachelor, or if married purchaser could choose his own place of residence. Premium for one-fourth share £2250.
5. PARTNERSHIP.—SOUTH COAST.—In a popular and favourite Watering-place the third Share (to commence) of an old-estab. mixed-class Practice, offering great scope for increase, is for disposal. Cash receipts nearly £1900 p.a., including panel (increasing) of over 1150. Visits 3s. 6d. upwards. About 30 cases of Mid. 8-roomed house with garden. Price for freehold £1450, of which at least £1000 can be obtained on mortgage. Premium 2 years' purchase.
6. SOUTH OF ENGLAND.—In a pleasant town (pop. 11,000) within 5 miles of favourite Watering-place, old-estab. mixed-class and increasing PRACTICE worth nearly £1300 last financial year, including transferable appts. and panel of 880. Excellent family residence, standing in its own grounds (tennis-court, flower garden, &c.) with ample accommodation. Held at present on lease (2½ years to run) at £90 p.a., and can eventually be bought for £1700 or less. Premium £2040, to include drugs, fittings, some furniture, &c.
7. PARTNERSHIP.—SOUTH OF ENGLAND.—The Two-fifths Share (producing an income of at least £1300 p.a.) can be acquired by a suitable gentleman in an old-estab. connection situated in an attractive town near the Sea. Appts. and panel held. Visits 5s. upwards, medicine extra. Very little Midwifery. Nice house available, held on short lease, but can be purchased. Excellent educational facilities, and sport of all kinds. Premium two years' purchase.
8. SOUTH-WEST OF ENGLAND.—PARTNERSHIP.—A one-half share in a very old-estab. Practice situated in an attractive small town, amidst beautiful surroundings, and within easy reach of the coast. Gross cash receipts for the past year over £2900. Panel of 1218 which, together with appts. brings in about £900 p.a. Moderate expenses. Visits 2s. 6d., plus mileage and medicine 2s. 6d. and 3s. 6d. extra. Very suitable house with 3 reception, 4 bedrooms and usual offices. Garden. Price for freehold £750, of which £350 on mortgage. Premium 2 years' purchase
9. LONDON, WEST.—PARTNERSHIP.—A half share in an old-estab. mixed general Practice. Average income for the last three years about £4000. Panel of 3250. Fees 2s. 6d. to 7s. 6d.; visits 3s. 6d. to 10s. 6d. and a few at 21s. About 30 Midwiferies at from 3 to 10 gns. Convenient house in good position. Held on lease (with no ground rent) with 25 years to run. Price £1650. Premium £4000. Must be Scotch.
10. CORNISH RIVIERA.—In a small but rapidly growing town (pop. 5000–6000) on the coast an old-estab. PRACTICE producing last year over £1000 including appts. and panel of 550 to 600. Opposition weak. Delightful residence, standing in own grounds of 1¾ acres (croquet and tennis lawns, &c.) and eminently suitable for Resident Patients which Vendor has been in the habit of taking. Contains professional rooms, 4 reception, 9 bedrooms, 2 bathrooms, &c. Water and electric light. Garage. Price for freehold £4000. Premium £1500.
11. LONDON, NORTH. — PARTNERSHIP. — A One-third Share, to commence with, in a very old-estab. mixed general Practice. Income approx. £3400, including appts. and panel of over 3000. Surgery fees 2s. upwards, visits 3s. upwards. If unmarried ingoing partner could reside with senior, otherwise suitable house available. Premium 2 years' purchase, half by arrangement.
12. LONDON, SOUTH-WEST (Within three miles of Charing Cross).—PARTNERSHIP.—A Half Share, with Succession to the whole in about 2 years, in a very old-estab. non-panel Practice, held by Vendor 26 years. Steady average income of £2300. Surgery fees 2s. 6d. and 3s. 6d.; visits mainly 5s. and 7s. 6d. Very little Midwifery. Good house in main road, with garden. Held on lease with nearly 15 years to run, at a rental of only £55 p.a. Prem. 2 years' purchase. Very good scope for increase.
13. KENT.—Country PRACTICE, within 6 miles of the Coast.—Old-estab. mixed General Practice. Income for past 12 months £1672, including appts. about £60, and panel of over 700. Fees 3s. 6d. to 21s. Not much Midwifery, 2 to 7 gns. Good house with 2 reception, 5 bedrooms, &c. Large garden and orchard. Garage for 2 cars. Price for freehold £1350. Sport of all kinds, and schools within reach. Premium £2250.
14. PARTNERSHIP.—SOUTH COAST.—In a fashionable Watering place the two-thirds share is for disposal in a mixed Homœopathic and Allopathic (roughly half and half) good class non-dispensing non-panel connexion in which there is a certain amount of surgery, and ingoing partner should be an operating surgeon. Receipts average over £3600 p.a. Fees up to 10s. 6d. Very little Midwifery. Large and suitable Maisonette available with ample accommodation, in excellent position. Garage. Rent on lease £250 p.a. Premium for share 1½ years' purchase.

TRADE MARK
A.D. 1715
"Bynin"
TRADE MARK
Amara
MALTED PHOSPHATES
WITH QUININE AND NUX VOMICA
A modification of the well-known Easton's Syrup (one-fourth the strength), in which the sugar of the ordinary preparation is here replaced by the valuable flesh-forming nutritive and digestive constituents of "Bynin," Liquid Malt.
It contains in solution the Phosphates of Iron, Quinine and Strychnine in "Bynin," Liquid Malt.
It is especially serviceable as a general tonic, and is a valuable restorative in cases of debility, promoting also the digestion of other foods.
DOSE FOR AN ADULT—A dessertspoonful to a tablespoonful, in water, three times a day, with or after food.

'Bynin' Liquid Malt 1 oz.

'BYNIN' AMARA

(TRADE MARK)

A Powerful Tonic and Hæmatinic

'Bynin' Amara is of special value in influenzal conditions and in the marked asthenia and nervous depression which are prominent features of the post-influenzal state. A course of 'Bynin' Amara whenever there is any indication of lowered resistance is a valuable safeguard against infection.

It has important advantages over Easton's Syrup on account of its basis being 'Bynin' Liquid Malt in the place of syrup. The 'Bynin' Liquid Malt, besides having valuable digestive and nutritive qualities is an efficient solvent for the other ingredients and helps to mask their unpleasant taste.

In bottles at 3/6, 6/6 and 12/-.

Further particulars and free sample will be sent on request
